When one studies the incidence of contagious disease in a school, one notices that epidemics are usually confined to certain rooms. In order to illustrate this I have charted all the cases of minor contagious diseases that occurred during this school year in two public schools. One school had twenty-one classrooms—seven on a floor. Four cases were reported from the third floor, three from the second, and thirty-seven from the first. There was one case of measles in each of four rooms, two cases in each of two rooms, and four cases in one room. One case of German measles appeared in each of three rooms and two cases in one room. One room had three cases of mumps and one had one case. One case of chicken-pox occurred in each of two rooms, two cases in each of two rooms, and three cases in one room. Three rooms had one case of whooping-cough apiece, one had two cases, one three, and one six cases.

The second school had three floors of four rooms each, but the first floor children were on half time, there being different classes in the morning and afternoon. No cases of measles were reported from the third floor. There were three cases in one room on the second floor and one case in another room. On the first floor there were no cases in two classes, one case in one class, two cases in each of two classes, three cases in each of two classes, and fifteen cases in one class. German measles did not occur on the third floor; one case appeared in one room and two cases in another room on the second floor. Of the eight classes on the first floor there were no cases in three, one case in four, and two cases in one. One room on the third floor had one case of chicken-pox, one room on the second floor had one case and another had three cases. Three classes on the first floor had no cases, four had one case each, and one had six cases. There was only one case of mumps on the first floor, one in one room and three in one room on the second floor, and two cases in one room and four cases in another room on the third floor. One case of whooping-cough occurred in one room on the third floor and two cases

occurred in one room on the second floor. On the first floor there were no cases in three classes, two cases in each of two classes, two cases in one class, three cases in one and five cases in another.

Intensive Study of an Epidemic in a School.—I have made a still more thorough study of an epidemic of chickenpox in a parochial school, where every child who had been absent for any cause was examined by the medical inspector before re-entering the class room, and where all unexplained absences of over two days were investigated at the end of the week by the medical inspector. It is of course much easier to detect convalescent cases of chickenpox than those of measles or of German measles. This analysis gives some idea as to the number of unrecognized and unreported cases occurring in a class room during an epidemic. It also shows how the different groups of cases in a class are separated by the period of incubation. This school has over two thousand pupils in thirty classes, occupying three separate buildings. There were no cases in one building of four rooms and in another building of eleven rooms. The third building has three floors of five rooms each. On the third floor there were no cases in four rooms and one case in one room. On the second floor there were no cases in four rooms and one case in one room. Two rooms on the first floor had two cases each, one had four cases, one had six, and one had twenty-two. The table shows in most instances the date each child was last in school, and whether the school was notified of the illness or whether the child was discovered sick in school or at home. I shall here merely refer to the class that had twenty-three cases. Seven of these were discovered in the class room, seven were discovered on their return to school after being absent, six were found by the medical inspector at their homes, and only three were reported by the physician or family. Indeed, in many instances the parents were unaware that their children had chickenpox, believing the eruption a manifestation of disordered blood, etc. The great majority had no physician. The sequence of absence from school of these twenty-three cases is as follows: One each on the third, fourth and fifth of December, respectively, nine on the eighth, three

on the ninth, two on the fifteenth and on the sixteenth, respectively, and three on the twenty-third.

Sufficient evidence has been presented, I believe, to bear out my contention that the unit in the spread of children's diseases is the class room; that an epidemic begins in one room of one school and thence spreads to neighboring class rooms and then to neighboring schools. Proper control will usually limit the epidemic to the original class room and will check the spread even here. The method of control is simple when one understands how the disease spreads in a class room.

The Prevention of School-Spread of Disease.—Infection occurs from a pupil in the classroom who is in the prodromal or incipient stage of the disease, or who has had the disease some days, or who is convalescent from the disease. Nearly all of these can and should be discovered before they have had much or any opportunity to infect the other pupils in the class.

Of primary importance in the detection of such children in the classroom is the teacher. It is she who sees every child at the beginning of and throughout the school session. If she is observant, she will know when a pupil seems sick or has an eruption, and if she is familiar with the outward symptoms of the common children's diseases she will be able often to recognize them in their incipiency, particularly during an epidemic and especially if at such times she is reminded to be on the watch and has recalled to her the symptoms she is to look out for. Medical inspection has failed to check the spread of disease partly because chief reliance has been placed on the medical inspector, who sees the children usually only at more or less infrequent intervals, and not on the teacher, who sees them every minute of every school day. There is no question but that the teacher is perfectly competent to recognize when a pupil is sick and she should be required to send to the medical inspector all pupils who seem ill. Should the medical inspector have gone for the day, the sick child should be seen by the nurse, when there is one, or be sent home by the principal. School laws which prohibit a principal from sending home a sick child are responsible for a considerable amount of the school-spread of disease. Another school rule that tends to keep sick children in a class where they infect others, is that requiring the dropping of a class that does not maintain a certain average attendance, irrespective of illness or epidemics. Many teachers refrain from sending sick children to the medical inspector for fear he may exclude them and thus lower the attendance, with the possible consequent dropping of their class. And for similar reasons principals sometimes discourage their teachers from sending sick children to the medical inspector. If disease is to be checked in a school there must be a rule,

which is enforced, that every teacher must send to the medical inspector, or to the principal, every pupil who appears ill, and that in the absence of the medical inspector the principal must send the child home. But the teacher and principal must be protected by a rule that absences on account of such exclusion shall not be the cause of dropping a class.

Medical inspection, properly conducted, is the second great bulwark against the spread of disease in a school. The medical inspector, if given the opportunity, can find the beginning cases and exclude them before they do much damage. He can also find the convalescent cases and prevent their reentering the class room. But for the latter he must have the cooperation of the school authorities. Many of those who have been out of school two days to two weeks with measles, rubella, mumps, or chicken pox, bring notes from their parents stating that they have had a cold, or indigestion, or a stomach rash, or hives, or a tooth abscess, or have been sick, or had no shoes, or had to help at home, etc. In most schools such children immediately reenter the class room and naturally transmit the disease to others, who wonder how they contracted it. A few schools send all absentees on their return to the medical inspector, but he seldom finds sufficient evidence to warrant excluding them. Besides, in many cities he is forbidden to undress or touch the child, and is thereby frequently prevented from detecting chicken pox, rubella, measles, and mumps. In order that the child convalescing from a contagious disease be kept out of school, there must be a rule, which is enforced, that all children who have been absent two days of more must wait in the doctor's office until permitted by the medical inspector to re-enter their class rooms. And the medical inspector must question the child closely as to the occurrence of eruption, sore throat, vomiting, etc., the presence of similar disease at home, etc. He often will have to frame his questions skilfully, as the child is sometimes instructed at home not to admit that she had a rash, etc. In addition to examining the tongue, throat, face, and hands, the medical inspector should be permitted to palpate for enlarged glands and when his suspicions warrant it, to examine the arms, chest, back, legs, and feet, of course in the presence of the teacher or principal. Any child who gives a history of having had a sore throat, should be cultured, as many mild cases of sore throat or tonsillitis are, as I have shown, in reality but cases of latent or mild diphtheria.

The beginning cases may be found as easily. All children sent to the medical inspector by the teacher should be examined carefully and their necks palpated when indicated. In the presence of an epidemic of measles all pupils in the infected room with coryza should be excluded; and in the presence of an epidemic of whooping cough, all children who cough should be excluded. Should the suspected disease not develop, the only harm done is the loss of a few days' schooling to one child. While waiting in the former instance for the eruption and in the latter for the whoop to develop, further subjects the class to contact with an infectious and hence dangerous person. When the medical inspector discovers a child with a contagious disease or has been notified of the recent presence of one in the class room, he should make a routine examination of the other pupils in the room for at least three days after the child has been in the room, to detect the first symptom of the disease in those who may have caught it from the same source that gave it to the absent pupil. He should examine more closely any pupil who had been absent recently, in order to discover the source of the contagion. In addition he should find out the last date the absent child was in school or the first day the child felt sick in school and from seven days later until fifteen days later examine the class every day, so as to discover at once any child who may have caught the disease from the one who is absent.

The school medical inspector of course should be competent and his action should stand unless questioned by the family physician, when a higher public health official should be called in. Some cities make a practice of having the contagious medical inspector pass upon all cases excluded by the school medical inspector. This sometimes prevents cases of adenitis being excluded for mumps, scabies, and pediculosis corporis for chickenpox, and urticaria and ivy poisoning for measles and rubella. But frequently the contagious medical inspector orders back to school a child convalescing from measles or rubella, in whom the eruption has disappeared, or one convalescing from mumps in whom the parotid swelling has subsided, leaving only enlarged cervical glands. The school should always be given the benefit of any doubt. It is impossible to keep disease out of a school if the health authorities insist upon returning to school infectious children who have been excluded on sufficient evidence by a competent school physician, merely because this evidence was insufficient or lacking by the time the contagious medical inspector arrived.

There is still left the pupil convalescent from a contagious disease who returns to school while still infectious, but in whom no evidence of disease can be seen and from whom no history of having had a contagious disease can be elicited. But even this case can be discovered if all concerned are willing to aid. The health authorities in the first place should insist on every physician reporting all cases of contagious disease he sees and should prosecute those who disobey the law. It will not be difficult to find them if the recommendations that follow are carried out. The parent or householder should likewise be compelled to report cases of contagious disease. There should be a rule, which should be strictly enforced, requiring teacher and principal to report to their medical inspector and to the health authorities all cases of known or suspected contagious disease among their pupils, of which they have knowledge. Parents frequently notify the teacher of the cause of the child's absence and other pupils are frequently cognizant of the cause. The attendance officer should report all cases of illness and all cases of suspicion to the medical inspector and should endeavor to learn the nature of the illness. All cases of illness that are not definitely known not to be contagious should then be investigated by the school physician or school nurse or by the health authorities. Some official should also similarly investigate the absences over two days among those who are under the compulsory school age. In addition the laity should be urged to report all cases of contagious or suspicious disease that come to their knowledge.

A practical point for the consideration of school and public health officials is that they must not attempt more than they have the means for carrying out. They must not demand of their subordinates more than they can properly do. Some heads, who realize the importance of all that should be done and yet are given insufficient men at insufficient

salaries, try to make their few underpaid men do more than they are physically capable of or than can reasonably be demanded of them. The result usually is that the whole work is poorly and improperly done by discouraged, spiritless, uninterested men. Municipalities must supply sufficient men and pay them adequately if contagious diseases are to be stamped out. And public health officials should be alive to the situation and should let the public know and understand their responsibility in the matter. Meanwhile they should do all that can properly be done with the assistance that has been afforded them. With teacher, attendance officer, and medical inspector, as we have them in most progressive towns, a great deal can be done to control the school spread of contagious disease, certainly much more than we are doing at the present day.

INTRASPINAL TREATMENT IN SYPHILIS, WITH ESPECIAL REFERENCE TO THE SPINAL FLUID FINDINGS.

By LOUIS A. LEVISON, M.D.,

TOLEDO, OHIO.

It is not to be questioned that great numbers of patients with syphilis who have been treated with as much efficiency and persistency as is possible with the older methods have gone on and developed tabes or other disease of the central nervous system. This clinical fact has given rise to the belief that the ordinary means of treating syphilis do not prevent or cure syphilitic involvement of the central nervous system. This is the reason why efforts have been made to discover some method of direct application of the therapeutic remedies at our command. These efforts have a rational basis since the demonstration by Noguchi and Moore that the organisms of syphilis are actually present in the tissues in paresis, tabes, and other luetic affections of the central nervous system. Analogous conditions have been demonstrated in non-syphilitic diseases of the central nervous system. Treatment in this latter type of case has to be by the intraspinal route to give satisfactory results. Flexner showed this in epidemic cerebrospinal meningitis, Lamar in pneumococcic meningitis, Wollstein, Flexner, and Amoss in poliomyelitis, and it is likewise being demonstrated in the treatment of tetanus. Inasmuch as the treatment of syphilis by salvarsan alone does not have many advocates, it can be said that the future does not offer immunity from syphilitic affections of the nervous system. The nervous system is involved, as shown by the examination of the spinal fluid, very early in the course of the infection. Fully 80 per cent of patients with primary and secondary syphilis show involvement of the spinal fluid. It is on account of this fact that it has been said that every patient with syphilis is a candidate for disease of the nervous system from the date of his first infection.

Our most reliable methods of determination of the condition of the central nervous system have to do with direct examination of the spinal fluid. This holds true not only for the preliminary examination, but also to follow the course of any therapeutic measure which may be instituted. The meninges are ectodermic and show pathological changes as early as the skin, which accounts for the early involvement of the spinal fluid. It is not the purpose of this paper to consider spinal fluid changes in detail, but certain points must be mentioned. It is very important to understand that there is no constant pathological picture of the spinal fluid in syphilis at any stage. The various tests which are made show the greatest variation in individual cases. The cell count is particularly variable. It may be high or low at any time, or may vary in the same patient within a comparatively short time. A low or falling count may take place in syphilis, along with other positive tests. A high count may fall prior to death in some cases. A spontaneous drop to normal or nearly so may take place in untreated cases, so that it is fallacious to consider a low count a criterion of cure or improvement. O. Fischer has shown that if spinal fluid is removed in portions and each is examined individually, the various portions will show different counts. It is advisable for this reason that clinicians should make counts on the first clear drops obtained after puncture. This would insure uniformity of results and comparable records. It is advisable also that the counts recorded in the case history should be made promptly after the fluid withdrawal. This would exclude the error which ensues if many cells go to pieces on standing. The number of cells counted should be stated in actual figures, and not by plus marks. Cases of tabes, with or without treatment, showing a low or normal cell count are very common, especially in the later stages of the disease. This is true, likewise, of the other biological phenomena and indicates the final, degenerative stage of the disease. The cell count in the spinal fluid is of far less value in diagnosis and prognosis than the Wassermann test.

It has long been recognized that disease of the central nervous system is more liable to follow mild systemic infections, often infections without apparent primary or secondary manifestations. The reason why certain cases of syphilis should lead on to tabes, paresis, or other disease of the central nervous system is not known. The specific organisms are in situ from the earliest infection, so there must be other factors involved than the mere presence of the spirochetes. If the activity of the organism of syphilis is confined to the vascular structures and meninges, the resulting condition will be less severe and more tractable to treatment than where the involvement is of the parenchyma of the brain or cord. This is the reason why cerebrospinal syphilis is amenable to treatment, and paresis is not. It has been pointed out that initial infections of the head or face are more liable relatively to be followed by involvement of the central nervous system than primary infections elsewhere. The syphilitic toxin may act on the central nervous system by means of a general dissemination through the blood stream. The perineural lymph space which surrounds every peripheral nerve extends along the posterior root to the spinal pia and is in direct communication with the adventitial lymph spaces of the perforating vessels. This affords a possible way for the toxin to be taken directly to the nerve structures.

Much work has been done recently on the permeability of the spinal and cerebral meninges. It has long been accepted by physiologists that few substances can freely pass from the blood into the spinal fluid. This is possible with such simple substances as sodium chloride, but not with the usual therapeutic remedies. The spinal fluid is in large part the product of the choroid plexus. Dandy and Blackfan have shown that the ventricles of the brain also play a part in the secretion of the fluid. The perineural and perivascular lymph spaces are in direct communication with and a part of the subarachnoid space. These spaces are not, however, part of the general lymphatic spaces of the body, although there is passage from the subarachnoid space into the general lymph stream. The reverse of this, however, is not true. Tilney and Woolsey have introduced solutions of trypan blue into the subcutaneous tissues, arteries, and veins in order to determine if the stain would reach the central nervous system. It was shown that the subcutaneous or intraarterial injections would readily stain the skin, thoracic and abdominal viscera, but not the central nervous system. The injections given intravenously reached the dura and pia, but did not penetrate the nerve tissue. Even using twice the amount and increasing the strength three times over the solution used for the intraarterial injection did not suffice to make the stain penetrate the nerve tissue. On the other hand, an intraspinal injection of one-tenth the amount of stain used in the first two experiments stained the meninges very deeply, went through the walls of the veins and capillaries, and travelled along the trabeculæ of the pia.

Sicard injected ink by lumbar puncture. He found particles of the ink in the ventricles of the brain in from two to four hours, and still later in the region of the peduncles and cerebellum. After twelve to twenty-four hours, particles were found in the substance of the cerebrum. He observed that these ink particles were removed by leucocytic phagocytosis, while substances in solution in the spinal fluid were removed by osmosis. Sicard states that the choroid plexus may be rendered more permeable to foreign substances by injury or inflammation. He argues from this that some of the beneficial effects of intraspinal injections may come from its damaging effect on the meninges, thus making it more permeable.

The question of the permeability of the meninges and choroid plexus to salvarsan has received much attention. Reasoning from the impermeability of these bodies to other foreign substances, it is the general belief that salvarsan given intravenously does not reach the spinal fluid or at least, if it does so, it is in amounts too small to be of any value in a therapeutic way. Numerous investigators have examined the spinal fluid for arsenic after salvarsan injections and have arrived at very contradictory results. It is the consensus of opinion, however, that the amount of salvarsan which reaches the spinal fluid is very small, and this amount is not to be relied on to influence favorably disease of the central nervous system. It is understood that if the involvement is of the vessels (endarteritis) or in the form of meningitis or gumma, a favorable result can be predicted from intravenous or intramuscular injections, either of salvarsan or mercury. It should be stated that very reliable workers, such as Benedict, have reported arsenic in the spinal fluid after salvarsan injection. Benedict examined four specimens of spinal fluid withdrawn twenty-four hours after an intravenous injection of salvarsan and found free arsenic in amounts running from one-sixth to one-tenth of the amounts found in the whole blood. The greater number of investigators have not been able to confirm this high percentage.

The inability to bring the therapeutic agent, when administered by the ordinary methods, in contact with the infecting organism deeply buried in the tissue of the central nervous system lead Swift and Ellis to intraspinal therapy. Numerous modifications of their original technique have been instituted, in addition to the method of direct injection of small amounts of neosalvarsan. A large literature has sprung up in connection with this subject with variable opinions and results. It is the belief of the writer that the bad results which were reported so frequently in the earlier period of this work are lessening in the hands of experienced and expert men. The Swift-Ellis method particularly is liable to be followed by an infection of the meningeal sac unless the greatest care and precaution are taken. The Ravaut method of direct injection of neosalvarsan is much more simple in its technique and less liable to lead to bacterial contamination. There seems to be a well-defined tendency in the literature to look upon this method as unsafe and dangerous. If this is finally the judgment of experienced men, the method should be discarded, but its great simplicity of technique and apparently good results should lead to a very careful weighing of the evidence before final opinion is passed. Many of the criticisms of intraspinal therapy have been upon theoretical grounds. It is stated that the relatively small amounts of arsenic present in twenty or thirty c.c. of salvarsanized serum could not lead to beneficial results. Approximate calculations of the amount of salvarsan or arsenic actually present in the dose injected have been made by a number of men. The blood is usually considered as one-nineteenth of the body weight and the blood serum as approximately one-third of the whole blood. There is a great possibility of error in calculations without actual analyses, because it is not possible to state how much of the salvarsan is fixed by the body cells and erythrocytes. The actual analyses published, such as those by Benedict and others, show but infinitesimal amounts of arsenic present, and it is difficult to reconcile these small amounts of chemicals present with some of the results attained. It is the firm conviction of the writer that actual improvement and benefit has taken place in some of his treated cases. To question these results or those of other men because of the inability to understand the method of operation is illogical and unreasonable.

Swift and Ellis studied the blood serum after the injection of salvarsan and showed that when serum was taken within six hours, it inhibited the growth of spirochetes, but if taken before treatment or after six hours there is no inhibition. This spirocheticidal activity of salvarsanized serum was further studied by Gonder, Castelli, and others. They found that heating the serum to 56° Cent. for one-half hour markedly increased its activity, and that this increase is due only in part to the destruction of some inhibiting substance. Stuehmer has shown that salvarsanized serum unheated exerts a curative action for twenty-four hours in mice infected with trypanosomes and a protective action

for forty-eight hours. If the serum is heated for thirty minutes at 56° the curative action is prolonged to three days and the protective action to four days. It is probable that the good effects of salvarsanized serum are due not entirely to its salvarsan content, but also to the formation of certain substances in the blood serum.

Intraspinal treatment is comparatively free from danger in the hands of men experienced in this work. Numerous bad results have been reported, but a great many of these are explainable by errors in technique. If it is admitted that parenchymatous disease of the central nervous system is not amenable to treatment by the older methods or by intravenous injections of salvarsan, it is the belief of the writer that a certain risk from this method is justifiable in the same way that surgical risks are assumed, even when there is an operative mortality of 8 or 10 per cent. Tabes and paresis lead to certain incapacity and death, and this method of treatment should be tried until its exact value is determined. It need not be said that the best results will be obtained in the early stages, when the diagnosis can be made from the spinal fluid findings. Physicians who have under their care or charge patients who have had syphilis should feel that every suspicious sign or symptom justifies a spinal puncture and examination of the spinal fluid. Results in early tabes have been comparatively good. There is a decrease in meningeal irritation with disappearance of pain, and an improvement in many other symptoms. Restoration of function which has been lost by actual nerve degeneration is not to be anticipated. It is noteworthy, however, that Weisenberg of Philadelphia reports one case of paresis where the pupils were almost rigid which responded promptly after sixteen intravenous injections of salvarsan and six Swift-Ellis treatments. Nonne reports similar observations in four cases.

All results after treatment should be measured by the changes in the spinal fluid. The cell count is easiest to influence, but has little prognostic value. The Nonne reaction may subside parallel with the cell count, especially after direct injections of neosalvarsan. Estimations for globulin and the total albumin content in the spinal fluid are subject to error after therapeutic injections of blood serum, on account of the albumin and globulin contained therein. The Wassermann and the Lange gold reactions are hardest to influence, and for that reason efforts should be continued until these reactions, at least the Wassermann, become negative, when that is possible. The method should not be disparaged because a few injections are unsuccessful. It is to be regretted that the difficult technique and expense of salvarsan makes a large number of injections impossible to many patients for financial reasons, but judgment should not be passed on a case unless there have been enough treatments, which may run as high as ten or even more.

The writer has given or has had given for him in his hospital service fifty-seven injections in seventeen patients. Some of these patients had but one injection and no conclusion whatever can be drawn from them, excepting the comparative safety of the method. The direct injection of neosalvarsan was practised in twenty-four instances, and salvarsanized serum used in thirty-three injections. The amount of neosalvarsan injected ranged from three to twelve milligrams. There were no deaths in the series, or other symptoms of severity. Pain in the back or legs was not uncommon during the first twenty-four hours, but was always relieved by an injection of morphine. A twitching or jerking of the legs was very troublesome in two cases, but subsided without after-effects. Bladder or rectal incontinence did not result in any case. All patients were kept in bed at least twenty-four hours after the injection and in some instances, as in the cases with twitching of the legs, were not permitted to get up for four or five days. It has not been the experience of the writer that the direct injection of neosalvarsan is dangerous, although a review of the literature leads to that opinion. The neosalvarsan has always been well diluted with spinal fluid before the injection and this may obviate some of its irrigating effect.

It was possible to get the spinal fluid Wassermann negative in three cases. The amount of fluid used in these reactions was 1 c.c. Whether the Wassermann will remain negative it is not possible to state. The cell count was variable and although lower in all cases after treatment, this is not considered a criterion of improvement. The three cases which became Wassermann negative were cases of primary optic atrophy, tabes, and tabo-paresis respectively. The case of optic atrophy became Wassermann negative after six intraspinal injections, three of undiluted salvarsanized serum heated at 56° and three of neosalvarsan direct (dosage six mg.). The oculist who examined this patient (Dr. Charles Lukens) states that his vision is improved by actual measurement, although the patient himself does not notice a great change for the better. The case of tabes showed after treatment a decrease in his ataxia, disappearance of pains, a general improvement in his well-being enabling him to go back to work. The third Wassermann negative case (tabo-paresis) has shown a remarkable change in his mental state after seven intraspinal injections. The writer is convinced that these patients have been improved and feels that the method should be continued until its status is definitely determined.

The relief of pain in patients getting but one or two injections has been noteworthy. This has happened from the direct injection of neosalvarsan as well as from salvarsanized serum. This shows that the result is not nessarily due to the preliminary intravenous injection of salvarsan, as has been claimed. It is not possible to exclude a psychological effect in judging relief from such a symptom as pain. Patients who were getting morphine, however, did not require it any more and it seems that the relief of pain can be ascribed fairly to the intraspinal injection. It is the impression of the writer that much of the unfavorable opinion from this method of treatment has been based on cases treated insufficiently. It is to be regretted that such persistency in treatment is necessary, and this fact may militate against its continued use. The writer believes that good results judged by the biological tests need not be anticipated unless five or six or more injections have been given. This number may be increased if necessary to twelve or fifteen before it is discarded as worthless in a given case.

The following case reports give the spinal fluid before and after treatment:

Case I.—Male, age 40. Tinsmith. Had primary infection at 21. Has ataxia, positive Remberg's sign, intense girdle and leg pains, numbness in extremities,

negative Babinski, absent patellar reflex, and fixed pupils.

Date	Treatment	Cell Count	Nonne	Spinal Wa. R.
Feb. 6, 1914	20 c.c. undiluted salvarsanized serum	66	+	+++
April 9, 1914	Ditto	52	+	+++
May 9, 1914	Ditto	41	+	++
May 23, 1914	Ditto	35	+	+
Feb. 5, 1915	Ditto	28	+	+

This patient has shown a marked symptomatic improvement. He does not have pain, the ataxia is less, and he is able to work every day. The reflexes are unchanged. This patient considers himself greatly benefited by the treatment.

CASE II.—Male, age 45. Primary infection at 27. Present trouble dates back about one year. Had sharp, shooting pains in legs and back. Slight urinary incontinence, memory poor, weakness, and impairment of mentality. Pupils irregular and react but slightly. Patellars absent, Babinski negative. No ataxia. This patient received three injections of undiluted salvarsanized serum in 20 c.c. doses and four injections of neosalvarsan, dosage 0.003 mg. His general condition has shown a marked improvement, pains absent, and the mental condition has cleared up. The urinary incontinence is not so troublesome, but is not entirely gone. The spinal fluid findings are tabulated below.

Date	Treatment	Cell Count	Nonne	Spinal Wa. R.
June 3, 1914	Salvarsanized serum, 20 c.c.	83	++	+++
June 11, 1914	Ditto	33	++	+++
June 18, 1914	Ditto	39	++	+++
June 30, 1914	Neosalvarsan, 0.003	11	+	++
Aug. 19, 1914	Ditto	20	+	++
Sept. 22, 1914	Ditto	28		++
April 5, 1915	Ditto	36		

CASE III.—Male, age 38, jeweler. Patient has no knowledge of any luetic infection at any time in his life. Has optic atrophy with falling vision, absent patellars, and fixed pupils. This patient has received three injections of salvarsanized serum in 20 c.c. doses and three injections of neosalvarsan direct in dosage from 0.003 to 0.006 mg. The Wassermann has become negative in the spinal fluid and his vision as determined by the oculist is better. The atrophy of the disc does not show any change to the ophthalmoscope.

Date	Treatment	Cell Count	Nonne	Spinal Wa. R.
Nov. 11, 1914	Neosalvarsan, 0.006	128	+	++
Nov. 23, 1914	Ditto	63	+	++
Dec. 14, 1914	Salvarsanized serum, 20 c.c.	40	+	++
Dec. 23, 1914	Neosalvarsan, 0.003	38	+	+
Jan. 9, 1915	Salvarsanized serum, 20 c.c.	56	+	+
Jan. 28, 1915	Ditto	12	—	—

CASE IV.—Male, age 42. Primary infection at 27. Has had symptoms for the past year. Severe pains in left arm and hand. No ataxia. Knee jerks absent, pupils do not react to light. Numbness in legs.

Date	Treatment	Cell Count	Nonne	Spinal Wa. R.
Dec. 23, 1914	20 c.c. salvarsanized serum	20	+	++
Jan. 6, 1915	Ditto	8	+	+
Jan. 20, 1915	Ditto	7	+	+
Feb. 10, 1915	Ditto	8	+	+
Feb. 22, 1915	Ditto	20	+	—

This patient shows marked symptomatic relief of his pains, numbness, and general well being. The patellars and pupils have not changed. The spinal fluid Wassermann is negative.

The remaining cases did not continue treatment sufficiently long to influence in a favorable manner the spinal fluid, excepting the cell count. These patients had from one to three injections each and for various reasons discontinued them. It was distinctly noted that some of the patients getting but one injection of neosalvarsan direct into the spinal canal showed great relief of pain. This relief does not appear to be a psychological one in consideration of the intensity of the pain in some cases. The withdrawal of spinal fluid may possibly be a factor.

Conclusions.—1. The effort to treat syphilis of the central nervous system by direct intraspinal injection has a rational basis in the inefficiency of treatment by the older methods and also from the results of intraspinal treatment by more recent methods in meningitis, poliomyelitis, and tetanus.

2. The cell count of the spinal fluid is a variable factor and cannot be utilized as a criterion of cure or improvement in a given case.

3. It is the consensus of opinion that therapeutic remedies administered by mouth or into the blood stream do not reach the spinal fluid in sufficient concentration to influence bacterial involvement of the central nervous system.

4. Intraspinal injections of salvarsanized serum or neosalvarsan in proper dosage is not a dangerous procedure in careful hands.

5. Intraspinal injections will relieve pain and a great many of the symptoms of syphilis of the central nervous system.

6. It is possible in some cases to render the laboratory tests of the spinal fluid negative if the treatment is continued sufficiently long.

7. The method should not be discarded, but continued until its proper place in therapeutics is definitely determined.

237 MICHIGAN STREET.

THE IMPORTANCE OF THE PERSONAL EQUATION IN THE TREATMENT OF THE TUBERCULOUS.*

BY WILL HOWARD SWAN, M.D.,

COLORADO SPRINGS, COLORADO.

IN this period of scientific and more nearly exact investigation and treatment of disease, there seems to be a possibility that we may sometimes fail to give sufficient consideration to the personal factors that may have much influence both in the causation and progress of the disease; that the "art" of medical practice may be neglected for the "science" of it. This is more likely to be the case in a chronic affection like tuberculosis; and it is about some of these various conditions that influence the progress of a patient ill with tuberculosis that I wish to speak.

First, I would not be understood as questioning in the least the importance of exact knowledge as to the pathology, bacteriology, and scientific data that are now or may be available. But I desire to state what is evident to a body like this—that as yet there are no specific agents or means of treating the disease and that, until such specific means are discovered, our chief aim must be to raise the resistance of the individual to the disease. In other words we must study and treat the individual who has tuberculosis rather than the disease itself.

Everyone realizes that all cases require an abundance of fresh air, good food, and proper regulation of rest and exercise. But are we not too often content to give our patients this general advice, leaving them to work out details which, for many reasons, they are incompetent to do?

Given a patient ill with tuberculosis should not our first thought be that he is ill not simply because

*Read at the thirty-second annual meeting of the American Climatological and Clinical Association, at San Francisco, June 18-19, 1915.

he has become infected, but because his resisting powers have not been sufficient to overcome the infection; and should not the second step be to hunt out and treat the causes which, in him, have produced such lowered resistance?

Of course one may have such an overwhelming infection that no resistance can control it. The question of hereditary predisposition or immunity will not be discussed here, but the fact of the very infrequent incidence of tuberculosis in Colorado and other health resorts where there is an unusually large proportion of tuberculous population, is good proof of the reality of acquired personal resistance.

Resistance may be influenced by so many factors in a person's physical, nervous, mental, and moral make-up; by his circumstances as to proper living; and by his adjustment to and viewpoint of his environment, that much study is often necessary to get at the real situation. But in many cases our success will be about in proportion to the care and accuracy with which we do it.

A person ill with tuberculosis may have reason for lowered resistance in some previous or coexistent disease, and the recognition and correction of these conditions may be the means of giving him the "lift" needed to enable him to overcome his tuberculosis.

Occasionally we are deceived as to the amount of food taken by a patient and it may appear, on careful observation, that this is the keynote to his failure to improve, and perhaps the reason of lowered resistance in the first place.

A man had been sick several years; never very ill, but with very limited strength and always very thin. He was unusually intelligent and there seemed no reason to think that he was not eating abundantly. Careful observation of his diet led to suspicion that he was underfed. He was more liberally fed with the result of prompt gain of nearly 20 lb. and marked improvement in all particulars.

Numerous instances could be quoted of marked improvement and even cure of tuberculosis after finding and removing the cause of prolonged digestive disturbances and analogous conditions. Mention will simply be made of a few.

A young man had been moderately ill with tuberculosis for several years without material gain. He had more or less indefinite digestive disturbance during this time. Finally a frank attack of appendicitis led to the removal of his appendix. His digestion from that time was greatly improved, he gained weight and strength, and his disease became inactive to the extent that he was able to complete his interrupted college course and has since lived a fairly productive life.

A woman had been thin and weak for several years, unable to eat or digest comfortably, was obstinately constipated, and constantly "bilious." A sharp "Lane's kink" was found and remedied with the result that she now is largely relieved of her digestive disturbances.

A young woman failed to improve during several years while living under nearly ideal conditions. She constantly had poor digestion, ate and slept badly; was nervous and introspective. She had a material cavity and her disease was slowly progressing. After long and careful consideration, and against the advice of able consultants, she was allowed to take up horseback riding, tentatively at first. There was prompt relief of her digestive difficulties followed quickly by general improvement. After about two years she was married. This seemed to improve some nervous complications and she has for seven or eight years lived a normal active life in an eastern coast climate, apparently well.

The recognition, during the past few years, of the importance of obscure focal infections in the causation of varied systemic and general diseases, has brought help to some victims of tuberculosis.

Two patients, a man and a woman, had failed to improve materially under intelligent and faithful care extending over many months. Both had continuous fever, poor digestion, were sallow and had moist pulmonary lesions. Finding and relieving an alveolar abscess in one and marked pyorrhea in the other changed the whole picture. Both quickly lost their fever, ate and digested well, color improved, cough and expectoration became much less, with drier chest signs and a gain of about 20 lb. in two or three months in ease case.

Similar improvement appears, in many instances, to have been brought about by the removal of diseased tonsils or the cure of diseased accessory sinuses. These conditions probably did harm both because of the prolonged slow absorption which occurred from them, and from the fact that they were the starting points of repeated infections, either of the respiratory tract or of a more general character.

Such occurrences bring up a very important and pertinent question. If the late removal of these depressing lesions has been of so much benefit, how much better that the conditions should have been discovered early, before extensive and perhaps irreparable damage had come to the patient.

The depressing effects of living under unhygienic conditions as to sunlight and ventilation, physical overwork, insufficient rest and sleep, and various forms of dissipation are so well recognized that they are not likely to be overlooked. But I am quite sure that we often fail to appreciate how frequently weakened resistance is caused by lowered nervous and mental tone from fatigue, worry, grief, discontent, homesickness, and unhappiness from whatever source.

I have never known a person ill with tuberculosis to do well while continuing to be homesick. This is a difficulty frequently encountered by physicians practising at health resorts. It is a condition not always easy of detection; for the homesick patient is very apt to conceal his state of mind with the idea that it is a matter of lack of will power and that he will fight it out alone.

In my experience it has many times been necessary to send for a patient's friends or some member of his family or to send him home in order to overcome this most distressing and depressing malady.

A young woman only moderately ill and apparently living happily and properly with friends from her home town, made no gain during a period of many months. She insisted that she was happy and her friends did not suspect that she was homesick. She ate and digested poorly and lost weight without apparent reason in her physical condition. Finally she admitted that she had been constantly homesick and at times almost desperate. She was sent home, to very unfavorable conditions, where she promptly gained markedly in weight and in all particulars—though eventually she died.

A mother of two small children, whom she had left at home, during many months failed to do well; slept and ate badly and was very nervous, though apparently always cheerful. For a long time she insisted that she was contented and satisfied with the existing plans. Finally she gave way, said she had been constantly homesick and that she must go home without a day's delay. On the trip her train was wrecked and she was subjected to severe nervous and physical hardship, which produced a condition bordering on collapse. As soon as she was able to travel again, she returned to Colorado to identically the same conditions as before, except that she brought the children whom she insisted on personally caring for. From that time on she ate, digested, and slept well without medicine, lost all nervousness and has since been doing much better.

In contrast with the above class of cases, patients are sometimes worried and nagged by their over-

anxious and indiscreet family or friends. It may be a very difficult and delicate matter to handle, but often a patient's improvement will depend on the physician's detection and management of these incompatible people. Someone's facetious remark that a physician must also be a policeman if he would successfully treat the tuberculous, contains much truth.

Worry about finances or anything else may do immense harm. Even though we may not be able to remove the cause of the worry, we may help the patient to be philosophical about it and to minimize its importance. The attainment of a cheerful state of mind may be almost as helpful as removing the trouble itself. I have often been impressed with the importance of cheerfulness, content, and hopefulness as a therapeutic measure, as well as the effects of various depressing mental and nervous factors in the causation of lowered resistance. In looking over the histories of 740 cases of tuberculosis treated during the past fifteen years, I find that 129 show reasons for believing that some form of nervous depression was at least an important causative factor. A large proportion of the earlier histories were carelessly taken and give no evidence at all bearing on the subject. I feel certain that it is much more commonly a cause than these figures indicate.

The great mistake and cruel injustice of sending people ill with tuberculosis far from home without sufficient financial resources to enable them to live under proper conditions and for a sufficient time without worry and embarrassment, has often been noted. But those who practise in health resorts still see so much distress from this cause that it cannot be over-emphasized. Getting well of tuberculosis is a long process and the cost of living and of care suitable to the patient's needs is usually greater in a health resort than in one's own home. A better climate will rarely overbalance lack of proper living conditions or worry and anxiety in obtaining them. Moreover, distinct harm is likely to come from advising a plan which the patient is financially unable to carry out.

The prolonged physical and mental rest and the limitations necessarily imposed during a "cure" sometimes become so irksome as to be a real detriment to the patient. In such cases finding out and making available suitable diversion and mental occupation may be the means of changing failure into success. The prescription must be suited to the individual, else harm rather than good may be done.

All these considerations help to show the need of personally taking the histories of our patients and getting into close confidence with them, in order that we may know all the factors in their lives which have to do with their powers of resistance. They should also indicate the danger of giving routine directions based on a physical diagnosis alone and of treating our patients as a class. We need to make a sort of social service diagnosis and to do the kind of work done by social service workers if we would most efficiently help our patients in the personal struggle to get well of tuberculosis.

Physiological Icterus of the Newborn.—Ada Hirsch finds that the blood of the umbilical cord contains more bilirubin than the blood of adults or of children after the icteric period. The intensity of the icterus of the new born is parallel with the degree of bilirubin content. These facts appear to controvert the hypothesis that icterus in the new born is the result of an infection.—*Zeitschrift für Kinderheilkunde.*

DIAGNOSIS AND TREATMENT OF GASTRIC NEUROSES.*

By S. WENDKOS, M.D.,

PHILADELPHIA.

CHIEF OF MEDICAL CLINIC OUT-PATIENT DEPARTMENT, MT. SINAI HOSPITAL; PATHOLOGIST OF JEWISH CONSUMPTIVE INSTITUTE.

RECENT medical literature is replete with discussions of gastroenterological subjects, emanating mainly from the surgical clinic and operating amphitheater. The contributions of surgery to our knowledge of gastric diseases has been invaluable. When I began to pay particular attention to gastric diseases some five years ago and to increase my knowledge had recourse to some standard text books on this branch of medicine, I was bewildered by the number of neuroses listed as distinct diseases; the whole subject was rather chaotic in my mind as a result of text-book reading. I then turned to surgery's contributions, such as, for instance, the work of Mayo's staff. Moynihan's work, Lane's, Deaver's, etc., and it was as though a thick veil shrouding the whole subject of gastroenterology had been lifted and I began to perceive clearly the distinctions, the diagnostic difficulties, and the medical as well as surgical aspects of many gastric conditions. The neuroses began to vanish in the light of day thrown upon them in the operating room by the aseptic knife. What was heretofore diagnosed and treated as a nervous hyperchlorhydria, was shown to be due to a gastric or duodenal ulcer, gall-bladder disease, chronic appendicitis or certain medical conditions as tuberculosis, chlorosis, nephritis, etc. Surgeons emboldened by their findings in large series of cases ventured to deny the existence of neuroses altogether. They challenged the internists and gastrologists to subject their cases of so-called nervous dyspepsia and other neuroses to the knife and they would be convinced that there was a pathological condition in the stomach or in the neighboring organs that would account for the dyspepsia. The glove thrown down by the surgeon was picked up by the medical man, and following the cases to the operating room he found that not a few cases which had been diagnosed as ulcer or other organic disease by the surgeon, revealed nothing to account for the gastric symptoms when opened up. I followed my own cases to the operating room and then I followed them home. The supposed chronic appendix which was removed, did not relieve the patient. This condition I have seen too often, and I have become convinced that many surgeons in a hurry blame the poor appendix for numerous gastric conditions which may be accounted for otherwise.

My own personal experience then leads me to the conviction that many gastric disturbances are nothing more than neuroses. But owing to the indefiniteness of this condtion I thought it was worth while to ask the question and attempt an answer, namely, What is meant by a gastric neurosis? It is generally admitted that the stomach, when not diseased in itself, is reflexly irritated through the autonomic system. Embryologically, the liver, pancreas, and appendix are offshoots from the primitive gut, all having the same nervous supply, largely through the sympathetic nerves. But as the human species developed a cerebral nervous supply was superimposed upon this primtive nerve apparatus, and the disturbances of these two regulators, sometimes working at cross purposes, produce many of the gastric neuroses. And so we find that the

*Read before Mt. Sinai Hospital Clinical Society.

cerebral or psychic control of our gastrointestinal tract is interfered with by a disturbance in the sympathetic nervous system. Exhaustion of one or the other produces many symptoms not accounted for by any pathological condition. Thus in neurasthenia, hysteria, and mental depression, we find that the stomach is involved.

In a great majority of stomach patients who consult a physician no organic lesion exists, even after the most painstaking diagnostic procedures have been employed in its discovery. Hence, they must be accounted for on other grounds than a chronic appendicitis, or latent gallstones or ulcer, as surgeons would have us believe. Let us designate these cases as neuroses. To be more specific, let us take up the various neuroses that I have seen myself in private and clinic practice: They are usually classed as sensory, secretory, motor, and psychogenic.

The sensory neuroses include the anamolies of the sensation of hunger, such as anorexia, bulimia, and parorexia. The first is by far the most important clinically, as we meet with it every day. Anorexia, the absence of the sensation of hunger, is a frequent accompaniment of many organic lesions of the stomach, notably cancer, gastritis, and later stages of ulcer. But it is frequently found as a pure neurosis accompanying neurasthenia and hysteria. Nervous anorexia sometimes leads to very grave results in nutrition. The onset might have been some error in diet, or some particular aversion to certain foods, or mental strain. The patient begins to select his diet, will not eat enough, and meat will be the first article of diet to be discarded. With the irregularity of the daily meals, irregularity of the intestinal evacuation will set in, and this will become the most notably conspicuous symptom to the patient. Intestinal stasis will lead to headache, insomnia, flatulence, and even intestinal pains. Von Leube also described a clinical condition which he called nervous dyspepsia, a condition in which the subjective symptoms are many and varied, but which do not harmonize with the physical and chemical examination of the alimentary tract. Many writers have doubted the existence of such conditions as nervous anorexia and nervous dyspepsia, but two cases under my present observation convinced me of their existence.

Case I.—Mrs. F., a lady of about 50 years, repeatedly complains that she has no appetite, and says she was treated for about a year for stomach trouble. It commenced soon after the death of her husband; she lost considerable weight, and the numerous stomachics that other physicians prescribed did not help her. When I first saw her she was so weak that she was in bed, cried easily, and feared that she, too, was going to die. On inquiry I found that she subsisted on a glass of milk and sometimes on less than that a day; while plenty of food was offered her, she partook of very little. On examination I found her rather emaciated, anemic, with a general viseroptosis. Before her husband's death she was up and about and attended to the household duties. It is evident that the mental worry and depression following her husband's death also depressed the hunger center which is situated in the medulla oblongata near the nucleus of the vagus. Special nursing and forced feeding, as well as an assurance of no serious stomach trouble, helped her to recovery.

Case II.—A woman of about forty looks the picture of health, and yet all she eats a day is not enough to sustain a child. She complains that even milk will produce epigastric pressure, make her vomit, cause her to feel bloated, and eructate; and she sometimes will go into collapse before vomiting. On the physical side, there is nothing discoverable that may produce reflex irritation in the stomach. She had a perineal tear and a slight retroversion of the uterus, both of which were corrected without however improving her condition. This patient is a profound neurasthenic or rather psychasthenic. In the hands of one who did not know patient as well as I do, she would have been a subject for gallstone operation, appendectomy, or what not. Fortunately, I happened to strike her fancy and was able to observe her for two years. She has been a patient in various other hospitals, and of several private physicians.

To say that a patient has neurasthenia and rest the diagnosis there is to fall into frequent error, because many organic diseases of the stomach, as latent ulcer or gall bladder disease, will in time produce nervous symptoms sufficient to brand a patient as neurasthenic, and surgery has demonstrated that many so-called neurasthenics really suffer from organic diseases, hence the witticism that it takes seven medical cures to discover an ulcer. Therefore to make a diagnosis of nervous dyspepsia and to persist in it, prescribe rest cures and world tours, the physician must be certain of his diagnosis, and to be certain one must know the patient, indeed from childhood, either through personal acquaintance or through a minute analysis of the life of the individual. This patient had been left an orphan by wealthy parents and intrusted to the care of a well-to-do uncle and aunt, who supported her from the estate left to her. She was treated kindly and her every caprice was gratified. In short, she grew up spoiled and capricious. Whenever she was in ill humor she refused to eat and only by extreme persuasion and bribes could she be persuaded to partake of any food. When she grew to adolescence, she assisted in a wholesale grocery firm, indeed she was one of the managers of it. In due time she married, receiving an ample dowry from her uncle. Her husband, however, was a ne'er-do-well, and in a short time the money that they had was eaten up. The fear of military service drove her husband, herself, and her two children to the United States. Here her husband became a skirt operator, earning from $12 to $15 a week and this woman, reared in comfort, had to manage a poor man's home. The result was that she could not accommodate herself and she gave way to the same capriciousness of her youth. And instead of a loving aunt with divers presents coaxing her to eat and drink, an irritable unsympathetic husband who saw her only at rare moments during the day, and the clamor and quarrels of the children helped to intensify her moods. She is subject to fainting spells, has spasmodic sensations of the esophagus, and is convinced that it is the food which she is persuaded to take occasionally that causes the symptoms.

I have related this case in detail to show how difficult it is to treat this and similar cases, for even rest cures and forced feeding for a while will not cure this woman's ailment, which is rooted in a lack of accommodation of her personal ego to surroundings. It is a real case of nervous dyspepsia.

Gastralgia is classified as a sensory neurosis, but I think it is dangerous for the general practitioner to consider any pain in the stomach as a gastralgia of nervous origin. It is so frequently associated with pathological conditions in the stomach or outside of it that while treating a gastralgia we may overlook a gastric or duodenal ulcer, tabes dorsalis, pancreatisis, etc. The other night a patient was operated on here and a perforated duodenal ulcer was found which cost the patient his life. Two days previous to the operation he was treated by some physician for gastralgia. One night I was visiting a physician and about 12 o'clock the physician was hurriedly called to see a patient. When he returned I asked him to tell me about the case. He answered that a woman patient of his had an attack of pain, a simple gastralgia. That patient had my sympathy.

Of the important secretory neuroses, achylia, hyperchlorhydria, and hypersecretion are mentioned. I have seen cases of achylia gastrica of neurotic origin. The classical experiments of Pavlov demonstrate it beyond a doubt. He held a piece of meat before a dog with a gastric fistula and obtained profuse gastric secretion. He then brandished a whip before the dog's eyes and the

secretion ceased. Continued mental depression or fear may produce a total or partial absence of gastric secretion. Hyperchlorhydria, as a secretory neurosis, is so frequently dependent upon reflex irritation that it is doubtful whether it exists as a pure uncomplicated neurosis. I have seen it in a family of three—mother, married daughter, and young girl, where there was a strong probability that it was neurotic. All are of nervous temperament, subject to emotional crises, when heartburn follows. Soda or milk is a regular stand-by. I should hesitate to treat a case of hyperchlorhydria as a neurosis without keeping in reserve the possibility of commencing ulcer, gall-bladder disease, or chlorosis, or chronic appendicitis.

In the wards I have seen a case of hypersecretion. The patient was an elderly gentleman, and he was admitted with suspicion of some serious gastric disorder. But as none was found excepting this hypersecretion the man was discharged without any improvement. Here again, development of the *x*-ray methods and Lane's claims dependent on various adhesions, suggest that it is possible that some extragastric adhesion is the underlying cause of his hypersecretory disturbance.

Of the motor disturbances such as nervous eructation, regurgitation, pyloric spasm, and cardiospasm, all are important because of their likelihood of being mistaken for organic diseases. I had an opportunity of observing three cases of nervous eructation for a long time. This condition occurs in air swallowers. I have seen a most typical case of this:

Case III.—Miss K., age 25, single, while spending her vacation at Atlantic City, one day partook of a heavy meal and to slake her thirst after it went out to drink some soda water. She drank rapidly two glasses and in a few minutes she felt as though something was being stretched and loud belching followed. She felt immensely relieved, after that she tried to belch voluntarily thinking it would relieve her occasional epigastric pressure. She then returned home and the next six months she kept on belching. She thought something was wrong with her stomach and began to diet without avail. I might add that her father died after an operation for gastric ulcer, that her mother is suffering from intestinal stasis and epigastric symptoms. So the home atmosphere was one to make her think of stomach disease and fear its consequences. While sitting in my office, and while I was writing down her history, I heard periodically about every five minutes, a rumbling and then when I tried to observe her, I also noticed that her facial muscles and throat were moving as though in the act of swallowing something. Undoubtedly she was swallowing the air which she subsequently belched up. Now it is quite possible that at the onset, the excessive amount of carbon dioxide stretched the cardium and left it patulous, thus making it easy to swallow air.

In two other cases, in men, this condition was quite distressing. In fact, one subjected himself to an operation without relief and only an intimate acquaintance with their life history convinced me that the conditions were neurotic. Both are tailors by trade, both have been subjected to thorough physical examinations in many hospitals and by private physicians without disclosing organic lesions.

Regurgitation as a neurosis I have seen once, and unless closely observed it will be mistaken for vomiting and serious gastric disease might be mistaken for it. The case of regurgitation that I have in mind is complicated by achylia gastrica. The patient is a conductor. After his evening meals and while on a car small quantities are regurgitated and spat out. It is characteristic that this will occur a number of times after a meal, while real vomiting happens only once or twice. This particular patient dates his trouble back to a wedding at which he ate some decayed chicken, after which he felt sick, vomited, etc. It is quite possible that the memory of this event lurks in his subconscious mind and automatically produces this reflex of spitting out morsels of food. This patient's nutrition did not suffer in the least, but usually, if the condition endures for a long time, emaciation sets in and the sufferer begins to look like an advanced consumptive.

This by no means exhausts the list of gastric neuroses, but I have discussed enough of them to indicate their variety and their importance.

The diagnosis of gastric neurosis should be held in abeyance until a thorough physical examination and a positive exclusion of organic disease directly or indirectly is made. The pre-existence of neurasthenia as a condition of gastric neuroses is not always true, because it may coexist with organic disease of long standing. Indeed, the cause of the neurasthenic symptoms themselves should be looked for. These can usually be found in an inquiry not in the conventional line of history taking, but an inquiry as to the social and personal life of the individual as far back as childhood days. This is important, as it has a direct bearing upon the treatment of these very difficult and baffling conditions. I am a firm believer in the Freudian practice of psychoanalysis in the neuroses. The old-time methods of treating these conditions whether gastric, traumatic, or post-operative, have not sufficed. Suggestion through authority and mystic therapeutics do not produce any lasting results. On the other hand, countersuggestion, reeducation, enlightenment of the patient as to his condition through an appeal to his own reason or intellectual capacity, have produced better results. Case III completely recovered after a minute explanation of the mechanism of air-swallowing and a suggestion that she could overcome it voluntarily. Dr. Williams, in an article on the treatment of traumatic neuroses, says that it is false notions that maintain the neuroses, and that it is by the substitution of these false notions by true ideas that cures are obtained. Psychic treatment, then, is of great importance. Where domestic relations are abnormal, these must be corrected first in order to influence the gastric neurosis.

Of the physical and medicinal therapeutics the following have been found of service: Intragastric or extragastric electricity tends to tone up an atonic condition of the stomach, acts as a sedative to a spastic condition. Hydrotherapy, massage, Swedish movements are of great help in nervous anorexia and nervous dyspepsia. Of drugs, iron, arsenic, strychnine, and the hypophosphites, and most important of all, the bromides, have been helpful. Finally, the diet: All the gastric patients do themselves an immense amount of injury by dieting themselves, by omitting to eat meat and vegetables, etc. Most of these patients are afraid to eat, and thus forced feeding under proper conditions is the best remedy. After such a regime a troublesome anorexia becomes changed to a voracious appetite. The fear of food disappears, normal health returns, but unfortunately for many of our patients such a regime is next to impossible. They cannot afford the necessary amount of the diet itself, nor the nursing or private hospital accommodations. In few hospitals can ward patients

be treated on the principles of the rest cure. The poor neurotics deserve our best efforts—medical, psychic, social, and preventive.

TREATMENT OF ACUTE EPIDIDYMITIS BY ASPIRATORY PUNCTURE.

By H. W. E. WALTHER, M.D.,

NEW ORLEANS.

CLINICAL ASSISTANT IN GENITO-URINARY AND VENEREAL DISEASES, TULANE UNIVERSITY SCHOOL OF MEDICINE; ATTENDING UROLOGIST, PRESBYTERIAN HOSPITAL; VISITING GENITO-URINARY SURGEON, CHARITY HOSPITAL

THE frequency with which the epididymis becomes involved in cases of Neisserian urethritis and the difficulty so often encountered by those called upon to alleviate the intense pain this complication produces, has led to the adoption of many different methods of treatment. The importance of speedily terminating any infective process in the epididymis should be apparent because of the liability of permanent secondary changes that at times ensue from such inflammation by which the functional (procreative) power of the testis is destroyed. In these cases it has been found that the sterility due to azoöspermia results from the nodular obstruction of the seminal ducts as a direct sequence of inflammation in the epididymis.

Epididymitis occurs as a complication of gonorrhea in about 25 per cent. of cases. The symptom which causes patients so much distress is *pain*. It is this symptom which usually brings them to the physician seeking relief. There is no gainsaying the fact that the pain experienced by many of the sufferers of acute epididymitis is agonizing. When they present themselves they are usually ready to undergo any operative ordeal whereby relief from this symptom alone is assured, and it is by operative means that results have been best attained—results that were prompt, safe, and permanent.

Many operative procedures have been described by various writers for the relief of this condition. I shall not attempt to mention them all. Prominently among the most popular have been: *epididymovasotomy*, as performed by Martin; *epididymal puncture* with fine bistoury, as advocated by Smith; *epididymotomy*, according to the technique of either Bazet, Hagner, or Belfield; the *aspiratory puncture* of Baermann and Ernst, and, finally, the *epididymal injection* with electrargol, as recommended by Asch.

In this modern day when surgery is attempting to wend its way along the paths of conservatism, it does not seem rational to perform an open operation when simpler means are at our disposal which are just as efficient. There is one means of dealing with epididymitis surgically in which the scalpel is not needed. I refer to the method of treating acute epididymitis by means of *aspiratory puncture* with a hypodermic syringe, as practised successfully by Baermann and later popularized by Ernst.

As early as 1852 puncture was practised by Pirogoff, and in 1854 Velpeau advocated the puncture of the tunica vaginalis in epididymitis, claiming that by relieving the tunica of its serous effusion content, thereby releasing the tension imposed upon the inflamed epididymis, he relieved the pain accompanying this complication almost instantly.

The technique we have adopted is as follows: The scrotum is prepared aseptically as for any operation; our practice being to shave the skin, thoroughly cleanse the same with green soap and sterile water, and then paint the site of puncture with tincture of iodine. The affected testis is then firmly grasped with one hand, the epididymis to be punctured pointing uppermost, and the skin over the selected area of entrance of the needle is put on tension. A very sharp-pointed, fairly large needle which is connected to a 10-c.c. record syringe, and which has been previously sterilized, is then thrust through the skin of the scrotum into the substance of the epididymis for ½ to ⅔ inch, and then the attempt is made to aspirate gently some of the seropurulent content. By withdrawing the needle slowly, aspirating all the while, one will often succeed in obtaining fluid from the different levels in the gland when the same would not be gotten if the needle was held in only one plane. Usually two or three punctures at different points in the affected organ are made.

The wounds are then sealed with a collodion dressing and a suspensory applied to the scrotum. Confinement to bed is not necessary and the after-care of these cases is very simple.

The only anesthetic which we have used has been that of spraying locally the site of puncture with ethyl chloride to freeze the part. In hospital practice even this spray has not been found necessary to gain the patient's consent to have the punctures made. A general anesthetic is never necessary for this procedure. In dealing with hypersensitive patients one might inject a few cubic centimeters of 2 per cent. novocaine solution subcutaneously and down to the epididymis so as to diminish the sensation when the needle punctures are made.

As a rule very little fluid is withdrawn. The effect of the aspiration, however, becomes manifest by an almost immediate relief from pain, and within 6 to 12 hours the swelling in the gland and the fever will be noticed to have diminished considerably.

The procedure is a painful one, at times very painful, but the aspiratory puncture causes a cessation of the patient's sufferings so promptly and shortens the duration of the infection so markedly that we believe this method of treating acute epididymitis is deserving of more attention and favorable consideration than has been accorded it in the past.

The Gas Bacillus and Digestive Disturbances in Childhood.—P. H. Sylvester and F. H. Hibben find that the gas bacillus is not a normal inhabitant of the intestinal tract. Its pathogenicity is apparently demonstrable in certain cases of infectious diarrhea, fat intolerance, carbohydrate intolerance, and chronic intestinal indigestion. The dietary treatment by means of fat-free lactic acid milk unpasteurized, by imposing conditions unfavorable to the growth and activity of the gas bacillus, is rational, safe, and more immediately effective than any other treatment so far advocated.—*Archives of Pediatrics.*

ROCKY MOUNTAIN SPOTTED FEVER TREATED WITH ADRENAL SECRETION.

By M. H. SMITH, M.D.,

BASIN, WYO.

THE remarkable views expressed by Sajous in his "Internal Secretions and the Principles of Medicine," very evidently offering a clue to a treatment for Rocky Mountain spotted fever, led the writer to subject three cases of the infection during the spring of 1915 to medication with adrenal secretion. Necessarily the treatment was experimental as there were no available data for determining the size of the dose or frequency of its repetition, medication being per os.

An attempt was made to secure a fresh preparation of the solution for each case; however, case number one was for the greater portion of the first week of treatment upon a solution of questionable activity. The adrenal product of one firm was selected and utilized throughout the treatment.

A tabular view of the symptoms and treatment of the three cases is here shown:

	Case No. 1	Case No. 2	Case No. 3
Sex	Male	Male	Male
Age	24	45	54
Incubation	6 days	4 days	3 weeks
Fever	High	Moderate	Relatively moderate
Fever duration	20 days	16 days	14 days
Eruption appeared on day of invasion	3d day	3d day	4th day
Eruption	Discrete macular with some papules	Discrete macular	Discrete* macular and papular
Delirium	Slight for 2 days	None	None
Pains	Not noteworthy	Annoying, articular	Quite severe, articular
Gastric disturbance	None	Marked	Slight
Complications	None	None	None
Dosage adrenal solution	M viij to x	M x to xij	M xij to xvj
Dosage frequency	4 hours	4 hours	4 hours
Convalescence	Rapid	Rather slow	Rapid
Sequelae	None	None	None
Calcium used	3 days	None	3 days
Result	Recovery	Recovery	Recovery

*Confluent on dorsum of hands, attempts at confluence on dorsum of feet under calcium administration.

In view of the colloidal changes from the infection, calcium was given experimentally in case number one over a period of three days. On the third day of such administration the normal rose tint of the eruption on the lower extremities began to darken, interruption of the calcium being followed by a cessation of the ecchymotic discoloration and its gradual return to the rose tint of the general eruption. This was repeated in case number three in which a brisk epistaxis on the third day of treatment required tamponage of the left nasal passage with gauze saturated with a solution of adrenal secretion, calcium being given internally for three days, the third day showing a development of ecchymosis upon the dorsum of the feet and ankles and an attempt at coalescence of an otherwise discrete eruption in the locality showing a petechial discoloration. Interruption of the calcium was followed by an inhibition of farther discoloration, that, however, which had been already produced being quite sluggish in its disappearance. Case number two had no calcium, no indication for its administration being apparent.

The three cases, except for the darker coloration mentioned, showed little violaceous coloration, the use of adrenal solution quite evidently preventing other than a deep rose color in the eruption. The eruption gradually faded without the mottling often noticed in cases under other forms of treatment.

In case number one there was a noticeable temporary fading of the eruption after each dose of adrenal secretion administered, this however not being at all marked in either of the other two cases. In every case, however, it was perceptibly shown that the eruption was darker before the four hourly dose of the glandular extract, the rose tint of the eruption being reestablished after the remedy was given.

Serially, the three cases under progressively larger doses of adrenal secretion had a shortened febrile disturbance or infection period. There was not apparent any control of the daily temperature excursion by the administration of the adrenal solution. The daily temperature range was quite satisfactorily controlled with acetphenetidin.

Although quinine had no part in the treatment of the cases here reported, the alkaloid has been quite generally utilized by physicians treating the affection, varying results being reported. Presumably the beneficial action from quinine may be explained in conformity with ideas of stimulation of the adrenal glands.

As bearing upon the colloidal aspect of the disorder, one might anticipate that sodium citrate would render assistance in the treatment, and while there was some intention to administer this compound experimentally, its trial was deferred to avoid confusion in treatment, the clouding of adrenal activity, detracting from the credit due the organic extract or an interruption of what appeared as a salutary progress.

Accessory treatment consisted of the administration of strychnine every four hours, acetyl salicylic acid was given as required for pains, acetphenetidin for controlling temperature, a daily saline and milk diet.

It was determined that in event of untoward symptoms, normal salt solution should be used, but no necessity was evinced for its utilization. The sphygmomanometer showed a relatively normal blood pressure.

The decided shortening of the febrile duration of the infection upon increased dosage of the adrenal solution, and the absence of other than a slight darkening of the rose-tinted eruption except as noted, may well be believed to be due to an influence extended by the glandular secretion.

WHAT PATIENTS WITH TOXIC GOITER SHOULD DO AND WHAT THEY SHOULD NOT DO.

By G. P. COOPERNAIL, M.D.,

BEDFORD, N. Y.

THE following will apply either before or after a toxic goiter is operated on.

You should avoid all excitement or irritation. Keep from work or pleasure that would cause you to become nervous or excited. Be very cautious about your exercise.

You should not take any alcoholic drink; no tea or coffee; no tobacco.

You should not eat any of the red meats or any kind of broth or soup made from them.

For your diet you may use a great deal of milk and things made with milk. Eat butter, eggs, stale bread, rice and all other cereals well cooked; chicken or fish only with the consent of your physician.

Eat an abundance of cooked fruits and vegetables. Very ripe, raw fruits and fruit juices are allowed.

Milk, butter, cream, and buttermilk are especially good for you.

Drink an abundance of good water; if you are not sure of its being good, boil it for twenty minutes.

Get all the fresh air you can both night and day; live out of doors as much of the time as you can.

You should have abundance of rest; go to bed early and take a nap through the day.

For a patient after operation for toxic goiter. Much depends on the success of the operation in your after care. Keep in mind your diet and avoid exhaustion either mental or physical.

Most of the above I gathered at Kocher's and Ochsner's clinics.

Medicolegal Notes.

"Chiropractics" Is Practising Medicine, and Requires a License.—On appeal from a conviction of violation of Massachusetts Rev. Laws, Chap. 76, Sec. 8, by practising medicine without being lawfully authorized, the defendant contended that he was a chiropractor, and that his acts did not constitute a violation of the statute. The evidence tended to show that he kept an office in Boston, indicated by a sign on which was his name followed by the word "chiropractor"; that he practiced for pay; that he said that the basis of chiropractic is the adjustment of the vertebræ of the spine; that the vertebræ when not in their normal positions press upon the nerves at the spine; that the malposition of these vertebræ was the cause of abnormality and that the adjustment of these vertebræ to their normal positions would remove the pressure at the spine; that he said that he did not coure, that he simply adjusted. He testified that "chiropractic is the specific science that removes pressure upon the nerves by adjustment of spinal vertebræ; there are no instruments used; it is done by the hand only." The treatment pursued by the defendant was to have those who resorted to him go into an inner room and remove their outer garments until they were stripped to the waist. The patient then took a sitting position. The defendant examined down the spine, beginning at the top, by feeling with his fingers to see whether each vertebræ was in its proper position. The method to discover whether a vertebrae was out of position was by making a gliding move of the three middle fingers of the right hand, which constituted the process of "palpation" whereby one vertebrae was compared with another. As a result of this "analysis" the defendant was able to tell whether vertebræ were out of alignment or out of their normal positions. In making "adjustments" the patient was placed face downward on a low table and the vertebrae which was out of condition was given a quick thrust or push by the hands of the defendant. The acts performed by the defendant constituted, first, an examination of the vertebrae of the spinal column and a determination whether they were in a normal or in an unnatural position; and, second, a manipulation of such of the vertebræ as were found to be out of position, so that they would become regular and correct with reference to each other. Although the defendant did not prescribe medicine, and testified that he paid no attention to the patient's description of symptoms or disease, yet it was obvious that his purpose was to treat the human body in order to make natural that which he found abnormal in the narrow field of his examination. "Chiropractic" is defined as: "A system of healing that treats disease by manipulation of the spinal column (Webster's International Dictionary). The court said that the defendant's manipulation was of a most important part of the body and related to a nerve center. It might have been found that it could have no other aim than a prevention of disease or relief from existing disarrangement of body functions. That which the defendant did and its manifest purpose might have been found to be practising medicine within the meaning of the statute. Medicine relates to the prevention, cure, and alleviation of disease, the repair of injury, or treatment of abnormal or unusual states of the body, and their restoration to a healthful condition. It includes a broad field. It is not confined to the administering of medical substances or the use of surgical or other instruments. It comprehends "a knowledge not only of the functions of the various organs of the human body but also the diseases to which these organs are subject, and the laws of health and the modes of living which tend to avert or overcome disease as well as the specific methods of treatment that are most effective in promoting cures" (Knowlton, C. J., in Com. vs. Jewelle, 199 Mass. 558, 560, 85 N. E. 858). In order to practise medicine one need not cover the entire field of the science. If he devotes himself to a very restricted part of it he still may be found to practise medicine. It is matter of common knowledge that there has been great specialization in that profession in recent years. It was held to be of no consequence that the defendant abstained from the use of the words "diagnosis," "treatment," or "disease" in description of what he did, and employed the terms "analysis," "palpation," and "adjustment." The acts which he did and their manifest design were to be examined rather than the words used, in order to ascertain the true nature of the defendant's conduct. A physical examination of the vertebræ, a decision whether or not they were in normal position, and strong manual pressure upon them with the object of changing the position with reference to each other of those found to be irregular, and thereby relieving pressure upon nerves, may be found to have such relation to the cure or prevention of disease or the relief of pain as to constitute the practice of medicine. The statute was held to be constitutional. The protection of the public from those who undertake to treat or manipulate the human body without that degree of education, training and skill which the Legislature has described as necessary to the general safety of the people is within the police power of the State. This general purpose may be effectuated by requiring even of those who profess to confine their practice to a narrow specialty a much broader knowledge of the subject provided such qualification is regarded by the Legislature as necessary for the practice of any branch of medicine. The statute did not impair in any constitutional sense the liberty of the defendant. The protection of the public health is an object of such vital importance to the welfare of the State that any rational means to that end must be upheld. The defendant was placed in no worse position than others. The circumstance that Section 9 of the statute to an extent exempts certain classes, such as osteopaths and pharmacists and those practising Christian Science, mind cure, massage and others, did not render the statute unreasonable as to the defendant nor deny to him the equal protection of the laws. The conviction was sustained.—Com. vs. Zimmerman, Massachusetts Supreme Court, 108 N. E. 893.

Promise to Pay Expense of Operation on Another.—Action was brought by a physician and surgeon on his own behalf and as assignee of H. E. Southworth, also a physician and surgeon, for services rendered, in performing, at the request of the defendant, a surgical operation on the defendant's brother-in-law. The evidence tended to prove that, while Dr. Southworth had formerly treated the patient, he was not under employment by him at the time the operation was performed, that the defendant asked him to perform it, and, upon being told by Dr. Southworth that the latter had spoken to Dr. Thomas (the plaintiff) regarding the matter, personally requested him to perform the operation, and said: "I want you to give him all the service that is possible, every attention, and I will foot the bills." On the morning when the operation was performed, in conversation with both the plaintiff and Dr. Southworth, the defendant said to the former: "I suppose you have called me in here for the purpose of having me say that I will pay for these services," and the plaintiff said: "Well, if those are the facts, Mr. Boruff, that is all right." "Well," said the defendant, "you boys go ahead and fix him up the best you can and I will pay the bill." Upon the plaintiff telling the defendant that the operation was necessarily attended with great danger and uncertainty the latter replied: "Go ahead and do the best you can for him." Another witness testified that Mr. Boruff said to the plaintiff to do the best he could for the man, and he (the plaintiff) would pay the bill. Not only did this testimony strongly tend to establish an original promise on the defendant's part to pay for the services both of the plaintiff and Dr. Southworth, but the testimony of the defendant himself was corroborative of that view. It was held that the evidence was sufficient to support a finding that the defendant promised to pay the expenses in connection with the operation. Thomas vs. Boruff (Cal.) 148 Pac. 226.

COLLOIDAL SULPHUR IN RHEUMATISM.

THE therapeutic uses of sulphur have been mainly confined to its external application in various cutaneous diseases. Its internal administration has been recognized for a long time chiefly as a valuable aid in the treatment of constipation. Its mildly laxative property probably explains its reputation in household medicine as an alterative. At one time sulphur was largely used in the treatment of chronic bronchial affections but despite the clinical acumen of Graves, who extolled its virtues in this condition, this application of sulphur has been all but forgotten. In the treatment of chronic rheumatism and sciatica sulphur has appealed to some observers as a sovereign remedy. Recently there has been a revival in the use of sulphur as an antiarthritic agent chiefly in the new colloidal form in which it is now available.

Loeper and Vahram (*Progrès Médical*, August, 1915) report that they have obtained exceptionally good results in the treatment of acute articular rheumatism by means of intravenous injections of colloidal sulphur. Their experience comprised seventeen patients, some of whom were under observation in one of the military hospitals in France. The drug was employed in daily doses of 33 to 66 milligrams. In every instance the pain was relieved within twelve hours after the injection and sometimes as early as two hours. The temperature began to fall on the day following the injection. In relatively mild cases one or two doses sufficed; in the more serious cases four or five doses were necessary; in the most severe types of this disease as many as ten doses were required to effect what seemed to be a cure. In five of the cases the sulphur was employed after the use of the salicylates had failed to make any impression upon the course of the disease or upon the intensity of the symptoms.

The intravenous injection of colloidal sulphur is followed by a marked systemic reaction. This is manifested first by a violent chill which occurs forty to fifty minutes after the injection and lasts about twenty minutes and a rise of temperature. The latter reaches 38° to 41° C (100.4° to 105.8° F.) in the course of one or two hours and then suddenly falls to normal. This rise of temperature is more pronounced in cases of acute articular rheumatism than in those of the chronic type of this disease; it is also greater with the use of larger doses of the remedy. The injection of colloidal sulphur causes a rise in the blood pressure, an increase in the number of red blood cells, and a transient leucocytosis.

As to the mode of action of colloidal sulphur, the question arises whether this stimulates the resisting power of the tissues or whether its antirheumatic virtues depend upon its antiseptic power. There is apparently an elective though not necessarily a specific rôle played by colloidal sulphur in acute articular rheumatism.

PHOTAUGIOPHOBIA.

THIS word is proposed by Ernest Clarke (*Medical Press and Circular*, August 4, 1915) to connote a shrinking from the glare of light, in contradistinction to photophobia, which signifies literally a shrinking from light. Shrinking from the glare of light is very prevalent in otherwise normal people who are deficient in retinal pigment—as fair people and especially albinos. The condition is much more prevalent than is generally recognized. The normal individual is protected from the glare of light out of doors by contraction of the pupil and by a wide-brimmed hat, but even these do not protect him from the excessive glare of snow or of improperly installed electric lights. That the glare of light actually hurts the eyes is proved in the cases of "eclipse blindness" or solar retinitis and in the cases of "electric retinitis" from an arc lamp. In these the ophthalmoscope reveals pigment changes at the macula, and there is a central scotoma which often remains permanent. In the worst cases there is an inflammation in the outer layers of the retina often extending to the choroid. Glare may cause cyclitis. When intense, as from snow or the electric arc, it produces a traumatic conjunctivitis sometimes accompanied by opacities and erosion of the cornea.

The treatment adopted for photaugiophobia has been the use of smoked or colored glasses, the colors most used being green, greenish blue, and blue. The disadvantages of these glasses are that they cut off a considerable degree of luminosity, they are quite unsightly, and their use tends to render the eyes very sensitive. Sir William Crookes has performed a large number of experiments extending over a period of several years with the view of discovering a kind of glass that would provide the best protection against the rays that are supposed to cause glassblowers' cataract. He found that in glass work the infra-red rays are the most injurious, the ultra-violet rays being almost equally so, and the luminous rays are injurious only when in great excess. Crookes has succeeded in finding a number of kinds of glass that cut off the infra-red as well as the injurious ultra-violet rays. There are now on the market two glasses known as Crookes "A" and Crookes "B". The former is composed of 83 parts of fused soda flux and 17 parts of crystallized cerium nitrate. There is present a small amount of didymium which gives the glass a pale pink when viewed edgeways. This glass is

said to be ideal for photaugiophobia, since it cuts off 27 per cent. of the heat rays and practically all the ultra-violet rays, and transmits 99 per cent. of the light. Clarke regards this glass as of the greatest value in refraction work, especially in the correction of myopia. Crookes "B" has a slightly darker tint, but is not to be recommended for general use, being especially indicated when very great glare or heat is encountered.

In the treatment of photoaugiophobia, in addition to the use of a protective glass, such as one of the above, the following details should be attended to: A suitable hat or cap should be worn in bright weather; the eyes ought to be well protected from top-glare. Naked incandescent gas or electric lights should not be fixed on the "eye-line," but should be placed high up or quite low down and then carefully shaded. The reflected electric light provides the best form of illuminant. The decoration of rooms should be in "cool" neutral tints, dull sage-green being the best. Desks should never face the windows. This should also apply to the beds in dormitories and hospital wards. With proper attention to these details, particularly in youth, photaugiophobia may never show itself.

INJURIES DUE TO THE WIND OF EXPLOSIVES.

Even weeding out all the fantastical tales which drift over to this country from embattled Europe and which continue to excite their measure of wonder from naïve auditors until they are discredited entirely, there still remain more things in war and its horrors than are dreamt of in the textbooks of military surgery, to paraphrase the old quotation. There are disease syndromes which are new to the internists, there are neuroses which baffle the neurologists and there are mysterious deaths the causes for which are not apparent. During the present war there have been numerous stories of men killed who were struck by no weapon or missile but who died apparently of fright, when a large shell exploded in their vicinity. Sometimes they maintained the attitude they held last and were discovered later on by their comrades who at first could not realize they were dead, so natural were they—a sort of grisly wax-works. Sometimes instead of instant death the soldier falls stunned, then rises and goes on fighting, apparently unhurt albeit dazed. A day or so later he suddenly collapses and is dead within a short while.

These deaths from the wind of missiles are mentioned by writers in other times, although they seem to have been comparatively infrequent before this war, probably because explosives never before attained such high potentiality. Larrey, Napoleon's great surgeon, expressly denied that such a thing was possible, but he seems for once to have been wrong judging by the well authenticated reports which we have to-day. Of course we must not confuse this condition with the deaths due to injuries by spent pieces of shell where there may be no outward sign of injury. In these latter cases the force of the missile is transmitted through the skin into the viscera which are found post morten to be lacerated or hemorrhagic.

Dr. Paul Ravaut of the Academy of Medicine of Paris, has investigated a number of these injuries due to the wind of explosives and thinks that the symptoms are due to a sudden, great change in the atmospheric pressure in the immediate vicinity of the soldier. Lumbar puncture was done on some of the cases soon after injury and the protein content of the cerebrospinal fluid was found always increased. Occasionally it would be found to contain blood. Hematuria was present in one case. One of Dr. Ravaut's patients had a paraplegia and in a case reported by Dr. Sencert the man who died was found to have intrapleural and gastric hemorrhage.

IGNORED SYMPTOMS IN CHILDREN.

In these days of diagnostic refinements we are no longer justified, if indeed we ever were, in dismissing the aches and pains of children with the assurance that they will be outgrown. It is certainly unscientific and uncritical to say the least to entertain a picture of the evolution of the child into the adult as a sort of pulling and hauling process, not accomplished without much creaking of the machinery. Some such simplistic formulation, however, must be responsible for the use of such terms as "growing pains." It seems probable that, leaving out of consideration the fatigue pains following unusual muscular exertion in children, as occur after a long holiday filled with hard play, the presence of pains in the muscles and joints is always indicative of some pathological process.

Such at least is the opinion of Dr. Mary H. Williams (*Lancet*, June 19, 1915), who says that growing pains are in reality rheumatism despite the general impression that this disorder is very rare in children. Other conditions she says may rarely cause these pains, as tuberculosis or syphilis. They may also occur in pubescent girls at the time of the monthly period, but then the etiology should be easily elicited. In Dr. Williams' examination of many thousand school children she found that these pains were preceded by tachycardia and that the children suffered from a slight pyrexia almost constantly. The first demonstrable symptom was impairment of the heart. This took the form of a displacement to the left and a muffling of the sounds. The writer thinks that rheumatism can often be prevented if the above symptoms are noted in time and recommends excision of the tonsils and adenoids as a preventive measure. This therapy, of course, depends upon the truth of the assumption that rheumatism is caused or precipitated by the absorption of toxins through the tonsils or through adenoid vegetations, a point which we cannot consider as definitely proved yet.

Another condition rather frequently seen in early life and too often not recognized is epiphyseal trauma. In the *Lancet* of August 7 Dr. Davies speaks of the dislocation of the epiphysis caused by a blow from a cricket ball on the tip of the finger and the consequent arrest of growth and limitation of usefulness of that digit. He shows a radio-

graph taken twenty-nine years after such an accident and another picture of a similar trauma just received. In this country, of course, this form of injury is usually due to a baseball, and we are all familiar with the distorted hands of old baseball players, especially the catcher and infielders. Dr. Davies advises a prompt *x*-ray of all such injuries and certainly it will not do to overlook the possibility of this condition in the growing boy who comes to us with a swollen finger as the result of a "hot liner."

Physical Signs Referable to the Diaphragm.

These signs may arise as the result either of irritation of the nerves supplying the diaphragm or of mechanical factors which change the normal position of this organ. Richard Dexter (*American Journal of the Medical Sciences*, August, 1915) has made an interesting clinical study of this subject. He finds that inflammation or irritation of the pleural or peritoneal surface of the diaphragm does not give rise to local symptoms. The resulting pain is referred upward along the phrenic nerves to the third or fourth cervical segments or downward along the sixth to twelfth intercostals into the lower thoracic segments. The pain is usually accompanied by tenderness and cutaneous hyperalgesia. These signs may be of considerable importance in the differential diagnosis between intrathoracic or intraperitoneal disease in the absence of any signs in the lungs. When a part or the whole of the diaphragm is forced downward the contraction of this organ causes a more powerful inward pull along the line of its attachments, which action is especially marked when the anterior portion of the diaphragm is depressed. This results in a lessening of the outward excursion of the subcostal angle or an actual retraction along the line of diaphragmatic attachment. Whatever forces the diaphragm upward lessens the strength of its inward pull and consequently increases the normal outward movement of the costal margins. These changes are of particular value in the diagnosis of obscure diseases of the viscera lying immediately below or above the diaphragm, especially of cases of pericardial effusion or of subphrenic abscess.

Should We Treat Fever?

The age-old controversy between empiricism and rationalism is entertainingly reopened by Dr. Harrington Sainsbury in the *Lancet* for August 14. This writer, after calling attention to the antiquity of the discussion, points out that if we are going to withhold our therapeutic attack until we have probed behind each effect for its cause our endeavors will resolve themselves into a chase after *primum mobile*. Disease is after all but a collection of symptoms and if we succeed in removing or alleviating all these symptoms we have cured the patient. Of course some will say that we have not affected the disease process itself, but, as Dr. Sainsbury justly says, a hypothetical disease process which does not produce any symptoms and consequently has no effect upon a patient's health or well-being might just as well be nonexistent. Even those who object to antipyretics, or at least chemical ones, recommend hydrotherapy. Provided we have no positive evidence that these chemical febrifuges do harm why not use them, at first in small doses and gradually in larger ones, to relieve the suffering of the patient? Certainly continued high fever devitalizes the tissues and reduces the resistance to the disease process. The true empiricism is after all the Hippocratic method, the study of the individual patient.

An Atypical Case of Cerebrospinal Meningitis.

The "spots" which have in general characterized "spotted fever" have always shown great variation, so that cerebrospinal meningitis has masqueraded as typhus, typhoid, rheumatic fever, influenza, erythema multiforme, and various other conditions. During the present war in Europe two differential tests have proved their great value. One is Eugen Fraenkel's histological examination of suspicious macules, papules, and petechiæ. Typhus is quickly recognized by specific changes in the adventitia of the finest arteries of the pars reticularis of the integument. The other is lumbar puncture which usually discloses the presence of Weichselbaum's meningococcus. At a recent session of the Munich Medical Society (*Münchener medizinische Wochenschrift*, June 8) Craemer reported the following case: a man admitted for vomiting and motor excitation presented peculiar nevus-like formations in his skin. He was very restless and screamed in his sleep. The vomiting ceased suddenly. The patient was found to be quite deaf. Next day it was learned that his skin was naturally clear. There were no further symptoms, save moderate elevation of temperature. The examination of the ear gave negative results. Lumbar puncture showed the presence of the meningococcus. The supposed congenital nevi in reality represented a rash. Stiffness was never present at any time.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the receipt of the following contributions for the week ending September 25, 1915:

The Norfolk County Medical Society, Norfolk, Va..	$28.00
Carroll County Medical Society, Wolfeboro, N. H...	10.00
Muscogee County Medical Society, Columbus, Ga...	14.00
Total	$52.00
Previously reported receipts	7,814.84
Total receipts	$7,866.84
Previously reported disbursements:	
1,625 standard boxes of food at $2.20....$3,575.00	
1,274 standard boxes of food at $2.30.... 2,930.20	
353 standard boxes of food at $2.28.... 804.84	
Total disbursements	7,310.04
Balance	$556.80

The Red Cross in Siberia.—It is reported from Geneva that Austria, Germany, and Russia have concluded an agreement under which the American Red Cross will be authorized to send twenty-five physicians and fifty nurses to Russia and Siberia to care for German and Austrian prisoners of war.

Tuberculous Prisoners to Be Sent to Switzerland.—Twenty-five hundred tuberculous prisoners will shortly be sent to Switzerland from England, France, and Germany for treatment in accordance with an agreement between these governments. The prisoners will be taken care of at sanatoria under Swiss guard at the expense of the countries whose captives they are. The British section of the sick prisoners will be sent to various places in

Oberland, the French to Leysin, and the German to St. Moritz.

A Remedy for Gaseous Gangrene.—Experiments at the American Ambulance in Paris seem to show that quinine hydrochloride is more efficacious than carbolic acid in the prevention and cure of gaseous gangrene and other wound infections. The experiments were conducted with guinea-pigs, but the final test was made by Miss Mary Davies, a young Englishwoman assisting in the laboratory, who, unknown to her chief in the laboratory, inoculated herself with a virulent strain of the gas bacillus and then presented herself for treatment with quinine hydrochloride. This was begun at once and the daring experimenter was sent to the hospital for observation and further treatment. Quinine injections were given a second time. Symptoms of a slight degree of infection developed within twenty-four hours, but they subsided without operation becoming necessary. She recovered completely.

The Recovery of Dr. Woods' Body.—The body of Dr. Edmund F. Woods of Janesville, Wis., who was killed through the torpedoing of the steamship *Arabic*, was washed ashore Wednesday of last week at Ross Carberry, County Cork, Ireland.

The New York City Death Rate.—During the week ending September 18 there were 1,291 deaths with a rate of 11.60, as compared with 1,330 deaths and a rate of 12.43 for the week ending September 19, 1914. The difference of .83 in the weekly rate means a saving of 92 lives. The death rate for the first 38 weeks of 1915 is 13.49, as compared with 13.94 for the first 38 weeks in 1914.

Cancer Increasing in Pennsylvania.—According to the report of the Cancer Commission of the Pennsylvania State Medical Society, made at the sixty-fifth annual meeting of this society in Philadelphia last week, the death rate from cancer in that State is increasing out of all proportion to the increase in population and that immediate action by health officials and the medical profession has become imperative. Since 1906, the report states, the death rate has increased 23½ per cent. Last year the number of deaths from malignant growths reached 5,197.

The Superintendency of the Randall's Island Hospital.—We are informed that the New York Civil Service Commission has withdrawn the notice of examination for superintendent of Randall's Island, upon which we commented last week, and through agreement with the Mayor, the President of the Board of Aldermen, and Mr. Kingsbury, has created the position of medical superintendent at a salary of $5,000 a year.

Report of the Rockefeller Hookworm Commission.—The work of the International Health Commission of the Rockefeller Foundation in fighting the hookworm, both in the southern part of the United States and in other countries, is made public in the first annual report of the foundation issued. Up to December 31, 1914, the Commission had treated 19,425 hookworm sufferers throughout the world. In addition it had instituted an educational system by which many thousands were instructed in the dangers and means of fighting the disease. The infection belts the globe in a zone about 66° wide, centering at the equator. Practically all countries in this belt are infected. Work was begun in British Guiana, Antigua, Trinidad, St. Lucia, Grenada, and Egypt. In Ceylon the Government and the Planters' Association started work on a small scale, meeting the cost locally. The campaign also took in Panama, Nicaragua, Costa Rica, and Guatemala. Besides its work in foreign countries, the commission has undertaken to complete the work of the Rockefeller Sanitary Commission in fighting the disease in the Southern States of this country.

Noticeable Reduction in Rabies.—Figures compiled by the Bureau of Preventable Diseases of the New York City Health Department for the second quarter of 1915 indicate that the measures adopted last year to control the spread of rabies in this city have borne fruit. The number of cases of hydrophobia in animals examined in the laboratories of the Department of Health decreased from 64 during the second quarter of 1914 to 15 during the corresponding quarter of this year. A reduction also occurred in the number of persons examined for dog-bite, and in the number of dogs examined for rabies.

Vaccination of School Children.—A recent bulletin of the Health Department calls attention to the sections of the public health law as amended recently by the Legislature which provide that no unvaccinated child shall be admitted into any school in a first or second class city. The vaccination, the department points out, can be performed only by a regularly licensed physician. No virus can be used unless it has been approved by the State Commissioner of Health. The exemption from the necessity of vaccination applies only to school children in villages and country districts.

Sterilization of Mental Defectives.—The question of the constitutionality of the law prescribing the sterilization of mental defectives is to be determined by the Supreme Court of New York State in an action recently brought to restrain the prevention committee. The committee proposes to sterilize a young man, one of a family of sixteen, all of whom are said to be more or less defective. The man is at present an inmate of the Rome Custodian Asylum.

Dr. Charles K. Mills has resigned from the chair of neurology in the medical department of the University of Pennsylvania. He had occupied the position since 1893.

Dr. A. H. Comforth, city physician of Fitchburg, Mass., has resigned to accept an appointment to the superintendency of a hospital in Paterson, N. J.

Dr. Harry A. Elcock has been appointed medical examiner for New Britain, Conn.

Dr. Andrew J. Gilmour of New York has added to his feats of mountain climbing by getting to the summit of Mt. Geikie of the Canadian Rockies. His companion was Prof. Edward Holway of the Department of Botany in the University of Minnesota.

Dr. Frederick Cook of Brooklyn, whose claims to have climbed Mount McKinley and to have reached the North Pole have not been widely accepted, is reported to have been refused permission by the Indian Government to scale the heights of Mount Everest in the Himalayas.

Discharged Hospital Physicians Invited to Return.—Six years ago eighteen physicians, comprising the attending staff of the Elliot Hospital at Manchester, N. H., were dropped by the trustees owing to ill feeling engendered by a dispute with the superintendent. Three of the eighteen have since died, and recently the trustees have invited twelve of the survivors to return to the staff, without, however, deposing the present members, the work of the hospital having increased sufficiently to

warrant an increase in the number of attending physicians and surgeons.

Annual Meeting of the First District Branch.—The ninth annual meeting of the First District Branch of the Medical Society of the State of New York will be held at Nyack on Saturday, October 9, under the presidency of Dr. James E. Sadlier of Poughkeepsie. The secretary is Dr. Charles Ellery Denison, 143 West Seventy-sixth Street, New York City.

Medical Society Elections.—The Medical Society of the State of Pennsylvania, at the meeting held at Philadelphia from September 21 to 24, elected the following officers for the ensuing year: *President*, Dr. Charles A. E. Codman of Philadelphia; *First Vice-President*, Dr. J. Torrance Rugh of Philadelphia; *Second Vice-President*, Dr. Edgar M. Green of Easton; *Third Vice-President*, Dr. William Albert Nason of Roaring Spring; *Fourth Vice-President*, Dr. Myers W. Horner of Mt. Pleasant; *Secretary*, Dr. Cyrus L. Stevens of Athens; *Treasurer*, Dr. George W. Wagoner of Johnstown; *Chairman of the Section on Medicine*, Dr. J. Wesley Ellenberger of Harrisburg; *Secretary*, Dr. David Riesman of Philadelphia; *Chairman of the Section on Surgery*, Dr. Levi Jay Hammond of Philadelphia; *Secretary*, Dr. John L. Atlee of Lancaster; *Chairman of the Section on Diseases of the Eye, Ear, Nose, and Throat*, Dr. C. M. Harris of Johnstown; *Secretary*, Dr. George B. Jobson, Jr., of Franklin. The next meeting will be held at Scranton, Pa.

The Oregon State Medical Association held its forty-first annual meeting at Portland during the second week in September when the following officers were elected: *President*, D. W. Kukendahl, Eugene; *Vice-Presidents*, Drs. Robert C. Yenney, Portland, B. F. Ferrell, Bend, and H. J. Clement, Salem; *Secretary*, Dr. M. B. Marcellus, Portland; *Treasurer*, Dr. K. C. Manion, Portland; *Delegate to the American Medical Association*, Dr. Walter T. Williamson.

The Second District (Wisconsin) Medical Society, at its annual meeting at Kenosha on September 8, elected the following officers: *President*, Dr. A. S. Keech of Racine; *Secretary-Treasurer*, Dr. S. Sorrensen of Racine.

Charitable Bequests.—By the will of the late Elizabeth Bartlett of Philadelphia, bequests are made as follows: to the Episcopal Hospital $1,000, to the Woman's Homeopathic Hospital $1,000, to the Emergency Hospital of Easton, Md., $1,000.

By the will of the late Susan E. Brown of Philadelphia, the sum of $200 is bequeathed to the Mercy Hospital.

Postgraduate Study in the Philosophy of Surgery.—The New York University has just admitted to its graduate school courses in surgery by which it will be possible for graduate students of the more theoretical or philosophical side of surgery to secure the advanced academic degrees of Master and Doctor of Science. The course does not deal with the technique of surgical practice but rather with the philosophy of this science, with the application of biological laws to surgical diagnosis and therapy. A similar graduate course will, it is understood, be introduced next year at Harvard, Johns Hopkins, the University of Minnesota, and perhaps elsewhere.

The New York Homeopathic College has begun this year a five-year course by enrolling a subfreshman class in which the subjects of chemistry, biology, and physiology will be studied. The requirement for admission to this class is the equivalent of one year of collegiate study as determined by examination or a Regents' certificate.

Genito-Urinary Clinics.—The third winter course of public genito-urinary clinics held by Dr. Abr. L. Wolbarst, will begin on Thursday, October 7, at 8.30 P. M., at West Side German Dispensary and Hospital, 328 West Forty-second Street, New York, and will continue throughout the winter every Thursday evening. A similar series of clinics will be held every Tuesday afternoon at 3 o'clock, at Beth Israel Hospital (Dispensary), Jefferson and Monroe Streets, beginning on Tuesday, October 5. Physicians and medical students are welcome. Interesting cases may be brought for diagnosis and conference.

New Hospital Wards.—The Augusta Caroline Thorn Wards of the Philadelphia Polyclinic and College for Graduates in Medicine were formally opened on September 22, addresses being made by Dr. S. McC. Hamill, president of the Faculty, and by Dr. John B. McAllister of Harrisburg, president of the Medical Society of the State of Pennsylvania. The improvement represents the gift of Miss Mary Thorn, a daughter of the woman in whose memory the wards are named, and who was herself a generous and early benefactor of the hospital. The additions include a woman's medical ward, a woman's surgical ward, a woman's private ward, a recovery room, and a room for serious cases.

Obituary Notes.—Dr. Colin McDougall of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1878, a member of the New York State and County Medical Societies, formerly physician of the Actors' Fund, and for many years connected with the New York Nose, Throat, and Lung Hospital, died at his home on September 19, aged 73 years.

Dr. George F. M. Lamont of Newark, N. J., was drowned on September 19 through the capsizing of a motor boat in a heavy sea off Avon, N. J. He was born in 1873 and was graduated from the Long Island College Hospital in 1896. He was a member of the New Jersey State Medical Society and of the American Medical Association.

Dr. James O'Sullivan of Tama, Iowa., died at Machias, Maine, on September 2, of cardiac disease. He was born in Manchester, N. H., in 1868, and was graduated from the Bowdoin Medical College in 1902. He began practice in Portland, Me., and later moved to Iowa.

Dr. U. L. Taylor of Columbia, Ky., died suddenly on September 3 at the age of 83 years. He was a graduate of the medical department of the University of Louisville in the class of 1875. He was for a number of years health officer of Adair County.

Dr. Thomas W. Sargent of Luflin, Texas, died on September 3 after an illness of several months' duration. He was born in 1860 and was graduated from the Memphis Hospital Medical College in 1890. He was at one time mayor of Lufkin.

Dr. Erasmus D. Skinner of Mineola, N. Y., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1858, physician to the Children's Home of Mineola, and a member of the New York State and Queens-Nassau County Medical Societies, the Association of New York and New England Railroad Surgeons, and the Associated Physicians of Long Island, died at his home on September 21, aged 77 years.

Correspondence.

SYPHILIS, GONORRHEA, AND GOUT.

To the Editor of the Medical Record:

Sir:—I have read with considerable interest Dr. Max Strunsky's article on gout in the current issue of the Medical Record. So there is no such disease as gout? Maybe. So all the old physicians (and patients) who gave such vivid and classic descriptions of gout were mistaken? Maybe. Such things do happen. It has happened more than once that things which were universally accepted without question have proved to be wrong, and it is possible that Dr. Strunsky's abolition of gout as a pathologic entity will prove of great benefit to the medical profession and their patients. But isn't it rather strange, if gout is merely a manifestation of venereal disease, that venereal specialists who see thousands of cases of syphilis and gonorrhea yearly, but very, very rarely come across a case of gout presenting the symptoms so well known to us from our various text-books? The writer has seen several cases, three of them absolutely typical, of gout of the big toe, but none of them was in a syphilitic, gonorrheic, or pyorrheic patient. That gout is much rarer now than it was formerly is admitted, but that is due to our improved and more rational mode of living.

And that brings me to another point in Dr. Strunsky's article. He says: "What is to-day was yesterday. Things do not change in this world; it is only our conception of them that changes. If one sees so little of gout now, it is fair to assume that there was very little of gout before." This, I regret to say, is a very untenable, a very erroneous statement. Things do change in this world, and particularly do diseases change. Whether a change in the symptom complex of the disease is due to a change in the pathogenic agent or to a change in the soil, that is to an improvement in our food, mode of living, etc., does not matter. But there is no question that very many diseases have lost their severity of former days and are much milder entities to-day. To mention but one disease, syphilis. We never see those horrible cases now with which our esteemed predecessors in the medical profession were so familiar. And this improvement cannot be ascribed entirely to improvement in treatment, for the disease is of a milder type in people in whom treatment has been neglected. No, I believe we will still have to let gout remain as a pathologic entity a while longer.

William J. Robinson, M. D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL SANITARY INSTITUTE—HOSPITAL AT BRIGHTON—PROVISION FOR INDIAN SOLDIERS TO PRESERVE CASTE IN ENGLISH HOSPITALS—KITCHENER HOSPITAL—MATERNITY AND CHILD WELFARE AND MORTALITY—WAR NOTES, RED CROSS, ETC.—OBITUARY.

London, Sept. 10, 1915.

The Royal Sanitary Institute had an interesting meeting at Brighton on Friday and Saturday. It was opened by the Mayor, under the presidency of Sir H. Tanner, and a number of Indians, khaki-clad, of various castes, and many officers of the R. A. M. C., were present. Mr. H. M. Black of the Health Committee of the Corporation, in a brief address, said no other town in the country had so many wounded soldiers staying in it, yet the health of the community was unprecedently high.

Major S. James, chief of the hospital, which is equipped for 2000 patients and is run by officers of the Indiana medical service, described the provision made for enabling Indians to live in accordance with the customs of their own country, and pointed out various conditions which must be strictly observed to prevent patients losing caste. They had to serve eight separate diets, cooked in twenty-one cookhouses in the hospital grounds, for the patients. For the staff sixteen other cookhouses were in use in the village. The Hindu cooks have to be of the same caste as the patients they cook for, or else higher. No beef is allowed inside the hospital, as the cow is a sacred animal to Hindus. Bacon and pork are also prohibited. As Indians must themselves slaughter the sheep they use for food, and in their special manner, a slaughterhouse has been provided for them. Hindus sweep off the head of the animal with a single stroke of a talwar or sword. For Mohammedans the mouth of the animal must be pointed towards Mecca.

The hospital requires 60 or 70 gallons of water per man a day—not so much when it is remembered that an Indian must bathe before prayer, and that a good Mohammedan must pray five times a day. The flooding of the bathrooms is a common trouble, as the patients neglect to turn off the water. Before the electric light was in use they persisted in blowing out the gas, so there was always danger of poisoning. As Hindus who die must be cremated by members of their own caste, a site has been set apart for this, and the funeral ceremonies can be carried out as precisely as in India.

Mr. Clement (Deputy Surveyor) estimated the consumption of water at the Kitchener Hospital as over 100 gallons a day. He added that one amiable failing of the Indian was to turn on the hot water and wait till it cooled to a comfortable temperature for bathing.

Lieutenant-Colonel Kenwood, Professor of Hygiene, London University College, read a paper on camp sanitation, on which there was some discussion. In the afternoon the members visited the Kitchener Indian Hospital and the Royal Pavilion Indian Hospital.

On Saturday Dr. Booth, M. O. H., of Nottingham, read a paper on "Maternity and Child Welfare," in which he maintained that there had never been a period in which it was more necessary to raise a healthy offspring. The stock was sound physically and morally, but we should not rule our conduct entirely by science. At least we should cultivate common sense. It was suicidal folly and immorality to restrict families. Parents of an only child might lose that through war or sickness and mourn they had no other to comfort them in old age. Dr. Duncan Forbes, M. O. H. for Brighton, followed on "Infant Mortality," and suggested that income spent on education of children should be exempt from the income tax. He further said some bachelors might be taxed. It would be a foolish policy to raise the birth-rate of any one class at the expense of another. The varying good qualities of every class should be preserved. If our best qualities were to be maintained we must give relatively equal encouragement to each class.

The war intrudes into meeting of all kinds, so it was not surprising to find it occupying much atten-

tion at the one held in support of the School of Medicine for Women, when Mr. F. D. Acland began by declaring that the supply of male doctors is insufficient to meet the demands of the present day. That being so the question arises of providing not merely for immediate but for future necessities. Mr. Acland said there are some hospitals in London where the possibility of having to close for lack of medical men has been mooted. I suppose he must have been thinking of the junior and resident officers, for I believe that there are many highly qualified men ready to take on staff appointments. He enforced his statement by adding that the war is teaching the nation the importance of medicine to the people's welfare, showing them in a terrible way the cheapness of life and at the same time realizing its value. We were determined, he said, to win this war, but we must make it worth winning. It would be so if our people were made finer and stronger than others, and to this end he held the women's school is to play a part worthy of all support.

Mr. Berkeley Moynihan, following, said if five years ago the cost of one day's war at the present rate had been devoted to research work the scourge of tuberculosis would now be hastening to its conclusion, and we should probably be free from cancer.

Lord Faber, who had presided at this meeting, in his closing remarks confessed he was convinced that this war would lead to a regeneration of the soul of England.

The Red Cross Society has required additional buildings to convert into hospitals and infirmaries for the wounded. The Women's Emergency Corps is collecting and dispatching to the front sandbags at the rate of about 5000 a week. Letters of appreciation and earnest appeals for more are being continually received. The ambulance committee, which has 150 cars at the front and has thus far dealt with 86,000 wounded, is in need of more cars to convert into ambulances. Volunteer drivers who are ineligible for military service can render valuable assistance. There are also a number of voluntary aid detachments for persons having special qualifications, especially those with some experience of army forms and methods. This statement applies to women as well as men.

Dr. Ralph W. Johnstone, Medical Inspector of the Local Government Board, died on the 26th ult., aged forty-nine. He had been British delegate at the International Health Office, Paris; was one of the Commission on Mediterranean Fever, chief delegate for Great Britain at the International Sanitary Congress, 1911-12, and plenipotentiary to sign the convention at Paris in 1912.

Progress of Medical Science.

3. Technique of Transfusion by Means of Glass Tubes. By A. R. Kimpton and J. H. Brown.
4. The Use of the Schick Test in a Children's Institution. H. Linenthal and S. H. Rubin.
5. A Case of Anterior Poliomyelitis with Multiple Paralyses, Including the Hitherto Unrecorded Involvement of the Left Diaphragm. P. H. Sylvester.
6. Auricular Fibrillation and Complete Heart-Block. P. D. White.
7. Suction and Irrigation Apparatus for the Diagnosis and Treatment of the Antrum of Highmore. J. Prenn.
8. A New Method of Treating Flatfoot. P. B. Howard.

1. **Surgical Experiences in France.**—W. J. Mixter summarizes his impressions as follows: Gunshot wounds do best if let alone as much as possible, unless there is some direct indication for interference. All war wounds except those caused by bullets which do not "upset" will almost certainly go septic. Gunshot fractures, even if septic, show remarkable powers of repair. Military surgery is so different from civil surgery that those who would expect to serve as military surgeons should have some definite training to fit them for their duties.

2. **The Common Shoulder Injuries.**—E. H. Risley emphasizes the following points: The diagnosis in shoulder injuries is not made by clear cut signs and symptoms, but only by a careful process of exclusion and *x*-ray examination in every case. The *x*-ray is of the utmost importance in every case as it often reveals the underlying cause of a persistent bursitis to be some of the frequent lesions of the greater tuberosity or acromion, which are very often overlooked unless especial search is made for them. About 60 per cent. of subacromial bursitis cases are of the occupational type. The remaining 40 per cent. have as an underlying cause in the great majority of cases, some lesion of the greater tuberosity or acromion. The diagnosis of ruptured supraspinatus tendon should not be made until at least three months of non-improvement have elapsed. Cases of long standing bursitis with adhesions give a picture identical with that of ruptured supraspinatus tendon and give extremely satisfactory results from operation. Calcareous deposits in the subacromial bursa may be spontaneously absorbed. The term insertion fracture should be substituted for the non-descriptive term of sprain fracture. Occupational neurosis *per se* does not exist in the shoulder joint. Injuries to the brachial plexus are rare. The percentage of patients benefited will be greatly increased by early exploratory operation. Slight injuries to the greater tuberosity and acromion process and arthritis of the acromioclavicular joint are of far greater importance than generally supposed in prolonging disability after shoulder injuries. The author places especial emphasis on the importance of these seemingly trivial injuries to the shoulder joint as factors to be considered in the diagnosis, prognosis and treatment.

4. **The Schick Test.**—H. Linenthal and S. H. Rubin note that of 126 children, ranging in age from 5 to 16 years, thirty-six were found susceptible to diphtheria and ninety were found immune. Antitoxin in a dose of 750 units administered to the non-immune produced an immunity which did not last over four weeks in 50 per cent, in several as long as eight weeks, and in six children the immunity conferred by the antitoxin persisted after five months. With the exception of the six children with the persistent antitoxin immunity and one child who gave a negative reaction the first time and a positive reaction the second time, the results of two tests, five months apart, were uniform. The test is of great value in determining susceptibility to the disease and thus serves as a guide to determine in the event of exposure to diphtheria, who should and who should not receive prophylactic doses of antitoxin. Persons naturally immune will thus be saved the annoyance and the possible disagreeable results apt to follow the injection of horse serum.

1. Gynecological Aspects of Backache.—G. W. Kosmak states that when backache has been determined to be due to a retroverted uterus, relief ought to be obtained within a comparatively short period after the restoration of the uterus, if movable, to a more favorable position by the insertion of a pessary. Before this is done, however, it is well to do away with all evidences of pelvic inflammatory conditions. If exudates in the perimetrium are present, the application of astringent and sedative tampons at regular intervals, together with the use of hot prolonged douches, must be employed before pessaries are made use of. Pelvic tumors, including fibroids, annexal disease, broad ligament cysts, or collections of pus in the pelvis must be taken care of in the accepted manner. Inflammations of the uterus from any cause, whether acute infections or produced by subinvolution, need to be brought to a condition of subsidence before relief may be obtained. If it is determined that the backache is due to a dislocation of the sacroiliac joints, absolute rest in bed with the application of adhesive plaster strapping, or in the very severe cases a plaster cast may be necessary before a cure can be secured. In the milder cases the application of a tight pelvic band which is worn constantly by the patient will do much to overcome the distress. Similarly the wearing of low heeled shoes will do much to overcome a false position of the spine which often increases the pain in sacroiliac luxations. Coccygodynia may be treated by conservative or radical measures depending on the severity of the case. In the milder forms hygienic and medical remedies, including the application of the electric current, will do much to alleviate the distress. Attention to the bowels and any hemorrhoidal conditions present will also act in a favorable manner. Where these measures fail, and especially where a deformity of the coccyx can be elicited on examination, it may be necessary to remove this appendage. Sedatives, including morphine, chloral, etc., should be employed with the greatest care, as the complaint is apt to be a chronic one and the necessity for continued administration may lead to unfortunate consequences. This common complaint in women should not be dismissed without due attention to the detailed findings in every case that presents itself. A diagnosis as to the etiological factor or factors in each instance must precede any method of treatment. It is possible that two or more causes may be present in the individual case and these must be treated in order. The mere finding of a gynecological lesion is not sufficient finally to determine the treatment.

9. The Formation of Urinary Calculi.—B. G. R. Williams in a series of very simple experiments has ascertained that a deposit of certain salts in the urinary tract may be influenced indirectly by over-plus elimination, concentration of the urine, the presence of organic matter, and so on, but that a deposit *in vivo* is directly accounted for by the action of certain ferments, doubtless of microbic origin.

11. Refraction in School Children.—A. S. Tenner notes that myopia is a condition rarely present at the beginning of school life and gradually increases with the age of the child, so that at the age of sixteen years almost one-half of the cases have more or less myopia. Children with hypermetropic conditions became myopic, the percentage of emmetropia or normal eyes remaining about the same. The correction of the hypermetropia and astigmatism with the constant wearing of the correcting glasses will prevent the development of myopia in many instances. Myopia in its high degrees becomes more than a mere handicap in life's race, producing degenerative changes, detachment of the retina with ultimate total loss of sight; therefore, apart from the relief and improvement in vision afforded by the wearing of glasses in cases of hypermetropia and astigmatism, the early refraction of children to prevent the development of myopia is most important. Every child before beginning school life should have its refraction estimated. If correcting glasses are required, they should be worn. If a child has a high degree of hypermetropic astigmatism, mixed astigmatism, or myopia of medium or high degree, with vision after correction of only 20 50 or less, it should be placed in special classes with a curriculum that minimizes the amount of near work. London has already taken such a step, several schools having special classes for myopes. There should be close cooperation between school authorities, school nurse, and school doctor on the one hand, and ophthalmologists on the other. Education boards should employ some one interested in the conservation of vision of children, preferably an ophthalmologist, in an advisory capacity. Such an officer could work to improve many existing defects, such as improper desk adjustments and poor lighting. The regulation of type and paper in school books is another matter to come under such an officer's control.

12. Hydatidiform Mole.—J. F. Robertson outlines the treatment of this condition as follows: If a positive diagnosis is made, evacuate the uterus immediately. Uusually a tampon in the vagina stimulates contractions of the uterus sufficiently to cause expulsion of the mass. The uterus is then cleaned out gently with placental forceps and packed with sterile gauze for twenty-four hours. The patient should be kept under observation for years; one should look especially for menorrhagia or any irregularities in the menstrual flow. If menorrhagia is present, the uterus should be curetted and the scrapings examined microscopically. In case of doubt a hysterectomy is the wisest procedure.

2. **Nitrous-Oxide Analgesia in Obstetrics.** — C. H. Davis cites the following advantages of this method. Nitrous oxide and oxygen constitute the safest of anesthetics. Given to the stage of analgesia they may be administered with safety over long periods of time. Nitrous oxide can cause death only by asphyxia. Dentists give it to the stage of analgesia to thousands of patients every year. It is quickly eliminated and has no deleterious effects on mother or child. In no case does the analgesia lengthen labor, but rather shortens it because of better assistance on the part of the mother. The Freiburg method may be used only by the specialist, while nitrous oxide and oxygen analgesia may be employed safely and efficiently by all. It is as safe in the home as in the hospital. It may be used in all classes of cases, the results varying with the cooperation of the patient and the skill of the obstetrician. It gives an increased control over the patient, in that there are none of the hysterical outbursts so often seen in the delivery room.

3. **Morphine and Scopolomine Amnesia in Obstetrics.**—J. O. Polak concludes that the twilight-sleep state is a reality and is applicable in any labor in which there is no primary inertia, marked pelvic contraction, or the presence of obstetrical accidents. It is especially applicable to nervous women of the physically unfit type. It is a valuable adjunct in the management of borderline contractions, for it allows the woman a full test of labor. It is distinctly a first-stage procedure and bears the same relation to the first stage as chloroform and nitrous oxide bear to the second stage; it relieves the pain but does not inhibit the progress of labor. It is particularly useful in cardiac cases as it relieves the nervous apprehension and secures dilatation with less muscular effort. It diminishes the shock of labor, whether that labor be normal, prolonged or operative. It does not diminish the milk supply. It does not predispose to postpartum hemorrhage. It does decrease the number of high forceps operations. And, finally, it has a distinct place in hospital obstetrics and should be tried out by those who have control of sufficient material definitely to determine its position in obstetrical practice.

5. **Infantile Scurvy.**—A. F. Hess finds that the pathology of infantile scurvy, including Barlow's classical account, is almost entirely devoted to a description of the lesion of the bones; little or no mention is made of the heart, the lungs and other internal organs. On the clinical side, attention focused on the evidence of hemorrhage—in the gums, beneath the periosteum, in the urine, etc. In several instances, definite cardiac enlargement was ascertained by means of physical signs and Roentgen examination. Necropsies also show that the heart in some cases is hypertrophied and dilated. The examinations made during life, as well as those carried out after death, demonstrated that this enlargement was mainly of the right ventricle. Another symptom which should be accorded greater significance is edema, which is almost always present to some degree. This occurs early in the course of the disease and involves most frequently the eyelids. It is often manifested as a firm edema over the lower end of the tibia, infiltrating the skin, and is readily overlooked, as it does not pit on pressure. This extravasation, which is due to a nutritional disturbance of the smaller vessels, may also infiltrate the muscles. When this occurs in the thigh and causes swelling, it may be mistaken for the typical subperiosteal hemorrhage. It would also seem probable that the nerves are involved in infantile scurvy. The knee jerks are increased, and there are indications of superficial tenderness of the limbs and neuroedema of the optic disks. In the light of this symptomatology and pathology, infantile scurvy is supposed to assume actual relationship to beriberi, in which the right heart is also hypertrophied and the nerves invariably involved. This correlation is emphasized still further by a dietetic test modeled after the treatment of beriberi, which, as is well known, is brought about by a diet of polished rice which has been deprived of its pericarp, and is cured by the addition of rice polishings to the diet. In the author's study, the addition of middlings—the pericarp of the wheat—caused in many instances a prompt amelioration of the symptoms, although it did not suffice to cure the disorder. This indicates the advantage of giving a cereal which contains the outer layers of the grain when the diet includes no other antissorbutic food.

6. **The Fate of Free Bone Transplants.**—W. L. Brown and C. P. Brown point out that in all of their free transplants, either with or without peristeum, into the muscle, subcutaneous tissue or omentum, were uniformly absorbed if sufficient time were allowed. This occurred regardless of the size or age of the transplant, the sizes ranging from one-fourth grain to an entire ulna. All of their scapular spines completely covered with periosteum were invariably absorbed. A review of the earlier clinical cases of McWilliams, reported to disprove Murphy's theory that transplants in contact with living osteogenetic bone always become united, indicates that the operations were performed by faulty technique as compared with the present standards. The same also applied to his experiments cited under the same head. They did not have sufficient contact and immobilization to secure primary union. In the author's experiments with free transplants, those covered with periosteum seemed to be absorbed about as rapidly as those without, though experiments of McWilliams, Phemister, and Davis and Hunnicutt indicate that the periosteum is a protection from absorption to both free grafts and contact grafts. The periosteum is evidently a protection to the process of regeneration and union between the graft and parent bone, preventing the ingrowth of fibrous tissue, exactly as a nerve sheath is a protection to the reperative process in peripheral nerves. From a study of their own experiments and those of others, the authors do not believe that the same interpretation should be placed on the behavior of the single free transplant, and multiple transplants in contact with one another. The latter seem to have an influence on the life and reproductive capacity of the grafts. The authors do not believe it has been proved that the periosteum is an important factor in the restoration of circulation in the graft. On the other hand, the indications are that it is a protection to the free graft from the circulation and absorption, and performs the same function for the contact graft, while circulation is being established from the living bone, its regular source of blood supply. As the periosteum has slight vascular connection with the bone, it is hard to understand how it assumes this particular function in the transplant. The authors do not believe that a free transplant should be considered as permanent except after several years, or that it lives as long as its host. Otherwise, it would be of no clinical value.

5. Quinine in Treatment of Experimental Gaseous Gangrene.—K. Taylor states that quinine has shown a marked bactericidal activity against the gas bacillus. It has inhibited the growth of the latter *in vitro*, where it is ten times as effective as carbolic acid. It has reduced the mortality from gaseous gangrene in animals from 100 per cent. to 41 per cent. Quinine has shown strong laboratory evidence of value as a general antiseptic. Its general bactericidal power is higher than that of carbolic acid. It is especially effective in a menstruum of pus. It does not damage healthy tissue in local injections of effective concentrations. It is known to produce local anesthesia, frequently a desirable result. It produced no symptoms of intoxication in the animals treated. It is used in hypertonic solution. It shows a strong antitryptic action *in vitro*. Upon the evidence of these experiments a 1 per cent. solution of quinine hydrochloride is now being tried in the treatment of gaseous gangrene and other infections.

6. Agglutination Reactions after Anti-Typhoid Inoculation.—D. I. Dakeyne finds that a man inoculated twice has a much greater chance of developing and retaining a reaction than one inoculated only once. There is a gradual diminution in the reactions as the result of the lapse of time. This is specially marked at the end of the eighth month. Only one case out of nineteen examined within a month of incubation was found negative. This man had been inoculated once only in France, and his serum, though giving no reaction with the *B. typhosus* used, gave a marked reaction with a strain of the *B. paratyphosus B*. There was no history of paratyphoid infection. If this case be excluded, all those examined within a month of inoculation gave a reaction. It appears that after the end of the first month the reaction is liable to disappear rapidly.

7. Brain Lipoid as a Hemostatic.—A. D. Hirschfelder notes that Howell has shown that the socalled fibrin ferment is not a true ferment at all, but a lipoid substance which seems identical with the diphosphatide kephalin, first isolated from the brain by Thudichum. Since Fonio, on the staff of Kocher, and others have shown the wide usefulness of local applications of fibrin ferment as a hemostatic in rhinological, gynecological, and surgical conditions, and A. F. Hess has found that tissue extracts which are rich in thrombin (especially brain and liver extracts) injected subcutaneously are of great value in the treatment of hemorrhagic conditions in children, it seemed of interest to determine whether a similar usefulness might be found for lipoids derived from the brain. Fonio's fibrin ferment is derived from the layer of centrifugalized blood which contains the platelets and is therefore present in relatively small quantities. The kephalins, on the other hand, are present in relatively large quantities in brain tissue. They are only slightly soluble in cold alcohol, but readily soluble in ether. For the purposes of military surgery it is important to obtain an active substance by the simplest possible method. In the author's experiments it was first used for stopping hemorrhage from the vessels of the skull and dura of the rabbit in a class experiment in which the action of drugs on the exposed pial vessels was being tested. It was found that when a trace of lipoid was smeared over an oozing surface of bone and a gauze sponge held for compression for one-half minute to two minutes, the oozing of blood ceased much more rapidly than it did in corresponding areas where no lipoid was applied. Equally satisfactory results were obtained upon rabbits' jaws, from which the entire teeth and alveolar processes were extracted. The lipoid accelerated clotting and left the denuded surface of the bone as a clean surface with a thin layer of glistening fibrin. When the lipoid is applied to a region traversed by an eroded artery of medium size, however, the cessation of bleeding is not nearly as striking as when the lipoid is applied to surfaces of oozing from capillaries, because the force of the blood pressure in the artery pushes the clot away before it has time to become firm and adhere. When, however, the bleeding occurs in a pit or trough between tissues, so that the blood can form a little pool, the result is quite different. The fibrin ferment action of the lipoid becomes manifest in from one to two minutes, and in normal mammals the entire mass of blood becomes transformed into a clot which is decidedly firmer than that which sets in spontaneously, and the resistance which this firmer clot offers to the blood stream hastens hemostasis.

Anti-Mosquito Campaign in Germany.—Zucker states that 1915 was a mosquito year by reason of the unusual heat of the summer. In the same class were the years 1906, 1907, and 1911. Mosquitos amounted to a severe hardship in the Crimean and Russo-Japanese wars, although in the latter the plague was largely discounted among the Japanese by precautionary measures. At the front in the present war there are active four species of culex and one of anopheles. The culex pipiens is the chief offender. The edema from its sting is due to the presence in its saliva of formic and lactic acids. Secondary infection of the stings is not uncommon. The insect should not be killed while sucking blood by slapping it, for then its snout is driven further into the tissues. The first bites are the most severe; in fact a sort of skin immunity develops in time. Certain measures have been in vogue for years for waging war against the insects but they represent a mere jumble and are based largely on ignorance of mosquito biology, the latter being as yet but imperfectly known. There are many substances which keep mosquitoes away from the person. Aside from screening, air draughts and ordinary flypaper, there are the chemical substances—tarry oils and oils of certain flowers. Of special value are the alcoholic extract of insect powder, oil of clove-pink, or gilliflower, oil of cloves. Certain powders are useful for fumigation; these contain niter, valerian, capsicum, etc. Lime twigs placed in flower pots filled with earth are extensively used in some localities. The best applications for bites are alkalies, especially in the form of soapsuds which have some penetrative power. Alkalies neutralize the acids already mentioned and keep the skin supple. Menthol or thymol ointment or solution is a good followup application and benzine or benzol is useful for reducing the wheals.

Clinical Experiences with Tetanus on the Western Front.—Klieneberger, despite the experience of a year with war tetanus, was able to save but 5 out of 31 cases which developed about the same time in a number of hospitals. But 3 of the patients had received immunizing injections and two of these died of hyperacute tetanus, of so severe a type that nothing could have saved them. The treatment of all the cases was intensive and the best that could be said of it is that it did no harm. Death did not occur as a rule from the primary intoxication of the disease, but from the original injuries, sepsis, pulmonary complications and heart failure. The five survivors showed the longest incu-

bation periods. The chief characteristic of the entire material was the steady, evolution of the disease. This is in marked contrast to the irregular and salatory character of many reported cases, in which exacerbation and remission are in evidence. The deadly character of these cases is associated by the author with unknown factors connected with the weather, etc. They all developed at about the same time but without real cumulation for they appeared in scattered localities. If this view is correct there must always be cases which even under most favorable conditions do not respond to treatment. Naturally many will insist that prophylaxis was almost entirely left out of the case, for in 90 per cent neither before the battle nor after injury was antitoxin given.

Münchener medizinische Wochenschrift.

August 10, 1915.

Influenza as Based on Autopsies.—Hubschmann regards this as a timely subject because influenza is one of the great war scourges, responsibility for the prevention of which rests upon the shoulders of the physician, who is no less important in warfare than the surgeon and maybe much more important when great plagues flourish. Now that Pfeiffer's bacillus is recognized as the cause or a cause of influenza, we have something tangible to stand on in pathological reports. On the other hand this germ may behave as a saprophyte, while the number of microorganisms which are able to cause grippe like syndromes is constantly increasing, and includes perhaps a series of unfilterable viruses. The picture of influenza is more labile than that of any other affection. The author enumerates hemoglobinophilia as highly characteristic of epidemic influenza when present; but that only in cold weather is this phenomenon in evidence. The author examined a series of miscellaneous cases between January and March, 110 in all, using smears of bronchial mucus. In 40 cases the latter proved to be sterile, in 70 not sterile. In 31 cases Pfeiffer's bacillus was present in pure culture while in 39 it was associated with other germ life. In other words over a third of these 110 cadavers had had influenza or were carriers at the time of death. But cultures from the cadaver often fail, and the author seems inclined to believe that Pfeiffer's germ is not often a saprophyte. In regard to a symbiosis the latter bacillus has been found in the bronchial mucosa of a true typhus, which, as is known, often simulates influenza at the outset. Returning to hemoglobinophilia and genuine influenza the necessary connection has not as yet been worked out. If the present belief is upheld in the future we should possess a first class criterion for genuine epidemic influenza and be able to differentiate the latter from the pseudo-types, such as "pneumococcus influenza." There is a vexed question which bacteriology should finally answer, to wit: may severe influenza (sporadic) exist when there is no influenza epidemic? We also have special clinical types, such as an "influenza sepsis" and an influenza bronchiolitis and pneumonia, which require correlation. It is asserted that in only 50 per cent of true influenza are there Pfeiffer's bacilli in the bronchial mucus. Such fluids show some error in the conception of the disease, and seem to point to the possibility that Pfeiffer's bacillus is not pathogenic for true influenza. But upholders of this view like Klieneberger believe that Pfeiffer's bacillus is pathogenic for different local affections of the bronchi and lungs. The author proves to be slightly skeptical in the whole, as if our researches into the nature of influenza had best begin anew. But he sees an undoubted connection of some sort between Pfeiffer's bacillus and epidemic influenza which he thinks will some time be proved to be that of cause and effect.

Deutsche medizinische Wochenschrift.

August 12, 1915.

Salvarsan Fatalities.—Fischer concludes his long serial article on this subject with the following summary: It is positively known that salvarsan sometimes causes local necroses and hemorrhagic encephalitis. Other accidents, including fatalities, which follow upon salvarsan injections are positively not due to the medicament. There belong all cases in which no lesions, not even microscopic, and no evidence of chemical action can be discovered. Some of the fatal cases are more readily traceable to mercury when the latter has been given with salvarsan. In one suspected case of this sort, proof was forthcoming. It is now known that salvarsan does not produce acute yellow atrophy of the liver which may be due directly to the virus of syphilis. The toxic action of salvarsan does not correspond to arsenical poisoning. Cases whoch appear to justify this conclusion have been imperfectly studied.

Treatment of Syphilis with Salvarsan Alone.—Krefting claims that mercury adds nothing to the efficacy of salvarsan in the treatment of syphilis. Primary syphilis can almost certainly be cured with from three to five injections of salvarsan with fourteen days interval, the doses being large. Definite rules for the salvarsan treatment of secondary syphilis are not readily laid down. The remedy should be used for a long time and should be persisted in for a time even should the war become negative. There is no universal contraindication for salvarsan treatment.

Epidural Injections.—Enderle recommends these in old, recurrent cases of sciatica which have proved rebellious to all other plans of treatment, and also as an adjuvant to other methods in all cases of neuralgia of the lower extremities, the gastric crises of tabes, the enuresis of childhood and as a sedative in all functional ailments of the urogenital organs. The technical execution is easy and with the usual precautions quite safe. With patient in the knee-elbow position 20 cm. sterile physiological saline infusion are injected into the sacral hiatus, but not too deeply. The author has as yet had no untoward result.

Treatment of Typhoid Fever with Besredka's Vaccine.—Szécsy uses this vaccine when it is not more than 10 or 12 days old. He gives it in a certain dosage daily for four consecutive days, injecting it under the skin of the abdomen. The doses increase according to a certain prearranged scale. Abortive results are not claimed, but the duration of the disease is shortened by 6 to 8 days including the four vaccination days. Relapses are diminished in frequency and when they develop indicate one or two extra doses of the fourth day or maximum size; upon which they terminate by crisis or two day lysis. The mortality of the series treated was but 2 per cent of 58 cases.

Analeptic Action of Calcium and Bromine Ions.—H. Januschke and M. Masslow conclude that calcium ions in large doses are not capable of counteracting the acute hyperexcitability of the motor centers in the brain, medulla, or spinal cord, or the motor nerve endings in the skeletal muscles. The combination of calcium and bromine ions in acute cases of motor excitability is not more effective than the use of bromine alone; nor is calcium bromide more effective than sodium bromide.—*Zeitschrift für die gesamte experimentelle Medizin.*

Insurance Medicine.

The Scope and Function of the Medical Department.—In a paper read before the fifth mid-year meeting of the Medical Section of the American Life Convention Charles F. Coffin pointed out that it was quite apparent that the scope of the medical department of a life insurance company was an exceedingly wide one. First, it had its own specific place as a department of the corporate organization. It had its own specific daily duties growing out of its definite work. It was also quite apparent that it had a tolerably definite relation to the actuarial department, an important relation to the legal department, and a vital relation to the agency department.

The following extract from a paper read at the St. Paul meeting by Dr. DeVancy was read: "A medical director who confines his duties to merely looking over papers and appointing examiners does not earn his salary, if it is very large. His position is one of trust, requiring judgment, honesty, and unlimited diplomacy. If I were organizing a company, I would select, as medical director, a man who, along with his medical knowledge, possessed good business judgment and marked diplomacy, for his duties are largely executive, requiring these qualifications. A medical director who is not in himself a stimulant to the business of his own company is more or less of a failure. He should be a living, vital, active force in the official staff of the company." He also quoted Mr. Hopp, who said at the San Antonio meeting: "The ultimate object of all activities in the medical department, is the attainment of a favorable mortality experience. Success in that direction rests chiefly upon a careful selection of risks and an effective control of medical examiners." As a careful selection of risks, so far as the medical department is concerned, begins with the duties of the examiners, the efficient control of medical examiners may well claim our consideration as the one great direct responsibility of the medical department; and it is the responsibility receiving in the majority of cases the minimum of systematic attention.

After stating that the duties of a medical director were more onerous by far than is recognized generally the writer quoted Dr. Talbot, who at the New Orleans meeting, said: "As a rule, the best examiners for large towns or cities are young men with hospital training, who have not been in practice long enough to have their time fully occupied and whose hospital training offsets the short time they have been in practice," and then went on to say that they should be intelligent and well educated, both generally and professionally. They should be appointed only after a careful inspection and only such physicians should ever be appointed as show some aptitude for the work required; an interest in the business of life insurance, and a willingness to study its general principles; a responsiveness to the needs of the field, a clear conception of his duty to the company, and a genuine confidence in the strength and character of the company in whose service he enlists.

The examiner selected must now be trained and this training or special education must be so planned, so applied, and so persistently applied as to produce, as nearly as possible, the ideal to which reference has heretofore been made.

In the second place, the medical department had a tolerably definite relation to the actuarial department. It was further pointed out that the medical department had an important relation to the legal department, and finally attention was drawn to the vital relation of the medical department to the agency department. The medical department and the agency department, or to be more specific, the medical director and the agent were so closely related that each was useless without the other. It was important, it was indispensable that harmony and a spirit of sympathetic cooperation should be established and maintained between these two strategic persons.

The agent's work was hard. Competition was keen and not always ethical. The agent, as a rule, was on a commission, not on a salary, and a rejection of an application was, to him, a serious matter. He was subjected to great strain, to much annoyance by the indifference and indecision of his prospects; to discouragements and obstacles before which most of us would retire defeated, if not routed. These were facts which a true medical director would never forget and they furnished a basis for sympathy and patience even when the fatal word "declined" must be written across the application. The relation between the agent and the medical director must not only be friendly and sympathetic: it must be personal as far as possible.

Carelessness in Physical Examinations for Life Insurance.—In the *Providence Medical Journal* Dr. W. H. Peters writes on this subject. He says that we know that comparative indifference to physical tests on the part of many medical examiners for life insurance is likely to occur. It is often overlooked purposely by the insurance agent in the field, the man who gathers in the risks. To those agents life insurance provides a livelihood first of all, but they are all very practical men. They do not of course, want to see the company they represent lose any applicant. It is a hard blow to them, and one they are going to avoid, if possible, to have a prospect they have been working on hard for weeks, months, even years to get to the point of signing an application for insurance turned down by the careless examiner in the company's service just when the well-earned commissions are almost within their grasp. The author says he has witnessed life insurance examinations for good-sized policies by medical men of repute that were valueless. The examiners are not strict enough; they pass over in their reports a heart a little wobbly, or a little sugar in the urine, and so on. All they think is necessary is to use the stethoscope, go through the motions of putting a blood pressure machine on the arm, make one simple test for albumin, and let it go at that. Some examiners are very strict, letting no point escape them. There are a few who believe it their bounden duty to protect the company against risks that might die after having paid no more than one or two premiums.

As the agent who receives the application can in most cases pick and choose from the list of the company's examiners the doctor to whom he may send his risk it soon follows that the strict medical examiner keeps long on conscience while he gets short on assignments and the consequent fees, while the careless examiner may lose a little sleep in worrying over his reports, but is able to soothe himself with the larger share of the assignments. The applicant for life insurance, Peters says, should be thoroughly examined by a physician competent to make all necessary physical and laboratory tests, even if it takes three or four days or a week.

Book Reviews.

Disease of the Arteries, Including Angina Pectoris. By Sir Clifford Allbutt, K.C.B., M.A., M.D., F.R.C.P., F.R.S., Hon. M.D., LL.D., D.Sc., etc., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College; Hon. Fellow New York Acad. Med., etc. In Two Volumes. Price, $9.00 net. London: Macmillan & Co.; New York: The Macmillan Company, 1915.

In the preface to this work the Regius Professor of Physic at Cambridge points out the sense of imperfection that haunts the composer throughout his work, which is keenest when the task is completed, and apologizes for the faults of the book. Sir Clifford Allbutt, however, need have made no apologies. He is one of the greatest masters of the subject on which he writes in the world, in fact, it may be said that he has made the subject almost his own. His contributions to the literature of the arteries have been numerous and have sufficiently testified to his wide and intimate knowledge thereof. The greater part of the two volumes is devoted to a consideration of arteriosclerosis, 680 pages; to aortitis is given 70 pages, and to angina pectoris 330 pages.

Arteriosclerosis proper is described as "Subintimal hyperplasia with splitting of the internal elastic layer." To some extent in the arrangement of the chapters on arteriosclerosis the cart seems to have been put before the horse in that the chapter on morbid anatomy of arteriosclerosis comes after the description of its causes, its symptoms, and occurrence in the kidneys. However, this of course detracts nothing from the merits of the work. Arteriosclerotic sufferers, from the clinical point of view, are divided by the author into hyperpietic and involutionary or decrescent. From the standpoint of morbid anatomy arteriosclerosis is described as a degenerative process. Emphasis is laid on the structural design of the arteries and especial stress is laid upon the fact that extensive vascular degeneration often occurs without either chronic elevation of the blood pressure or its constant accompaniment, cardiac hypertrophy.

The best part of the book is that which deals with angina pectoris. It is indeed a masterly exposition of the writer's own knowledge of the subject, presenting, in effect, all that is known of the matter. Sir Clifford displays his critical acumen throughout the work, in selecting that which is true and discarding that which is false or which is open to doubt. It goes without saying that from the purely literary standpoint the work is beyond cavil. The language is English of the best, easy flowing and yet expressing the writer's views without redundancy. It will not be too much to say that the work will stand the test of time as a model both of knowledge of the subject and of literary merit. The books are well bound, well printed and are in every respect worthy of the author and subject.

The Popes and Science. The History of the Papal Relations to Science During the Middle Ages and Down to Our Own Time. By James J. Walsh, K.C.St.G., M.D., Ph.D., LL.D., Litt.D., Sc.D. Professor of Physiological Psychology at the Cathedral College, New York. Notre Dame Edition. Price, $2.00 net. New York: Fordham University Press, 1915.

Those who are familiar with this work will welcome it in its new edition which has been enlarged by the addition of 100 pages of appendices. These additions embody numerous documents, brief biographies of the Papal physicians, and a special section devoted to Draper's "Conflict between Religion and Science." Dr. Walsh's accepted position, not only as a churchman, but as a physician and a student of history, lends added weight to the forceful argument here presented. The book has already found a wide circle of readers and in its new dress will no doubt find its field distinctly broadened.

Urgent Symptoms in Medical Practice. By Robert Saundby, M.D., Edin., Lieutenant-Colonel, R.A.M.C. (T.) Price, $2.10 net. New York: Longmans, Green & Co.; London: Edward Arnold, 1915.

The contents of this volume completely belie its title. The symptoms described in it are not all urgent by any means and diseases are described as well as symptoms. It is "intended to be a handy work of reference for the busy practitioner or student who desires to learn quickly, without the delay and labor of consulting several volumes, the significance of a particular symptom." The author has missed the opportunity of producing a really valuable book by not living up to the title. One can readily imagine how much use would be made of a work which discussed symptoms only and told the diseases in which they might be found. Instead we have here an abridged encyclopedia or extended dictionary containing brief articles on many topics and including more or less treatment. The result is often far from satisfactory. The length of the article is often out of proportion to its apparent value, as, for instance, the one on albinism is longer than that on acidosis. Leucocytosis gets less than one page and is extremely inadequate, and Gait is given four lines. There are some grave errors, as where under the heading Monoplegia the author says that anterior pollomyelitis is caused by the meningococcus of Weichselbaum. Under hematemesis is discussed the treatment of bleeding piles. In fact, one gets the impression that the author started out with a worthy idea, but either found the job too big for him or else had too little time to finish it properly.

An Introduction to the Study of the Endocrine Glands and Internal Secretions. Lane Medical Lectures, 1913. By Sir Edward Schäfer, Regius Professor of Physiology, University of Edinburgh. Price, 75 cents. Stanford University, California. 1914.

In this monograph Professor Schäfer gives us an authoritative account of what is known of the ductless glands and the internal secretions. The book is evidently a copy of the lectures as they were delivered, for there is neither preface nor index. The lectures are entitled: 1. General considerations regarding internal secretions and the organs which furnish them. 2. The function of the thyroid apparatus. 3. The functions of the adrenal apparatus. 4. The pituitary body or hypophysis cerebri. 5. The internal secretions of the pineal gland; of the alimentary mucous membrane; of the pancreas, and of the sexual organs. The author uses the term "endocrine gland" to imply "an organ which is known to form some specific chemical substance within its cells and to pass this directly or indirectly into the blood stream." He attributes the activity of the internal secretions to "hormones" and "chalones, the former of which have a stimulating action and the latter an inhibitory action. He also introduces the word "autacoid" as a generic term to include both hormones and chalones. The work will be welcomed by all students of physiology and by all who are interested in the newer methods in therapeutics.

Alveodental Pyorrhea. By Charles C. Bass, M.D., Professor of Experimental Medicine at the Tulane Medical College; and Foster M. Johns, M.D., Instructor in the Laboratories of Clinical Medicine at the Tulane Medical College. Illustrated. Price $2.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

This is a book of particularly timely interest and importance in view of the recent discovery of the pathogenic rôle of the *Endameba buccalis* in the causation of so-called pyorrhea alveolaris. The authors present a history of the investigations with reference to the amebæ whose normal habitat is the mouth. They note that in 1849 Gros described an *Ameba gingivalis*. The credit for the discovery of the *Endameba buccalis* as the cause of alveodental pyorrhea and of the favorable effect upon the lesions produced by the local use of emetine hydrochloride, belongs to Smith and Barrett who announced their results in July, 1914, although Bass and Johns made this discovery independently but reported their results two months later. The latter investigators were, however, the first to show the prompt curative action of emetine hydrochloride when employed hypodermically. In this volume they describe the etiology of alveodental pyorrhea whose specific cause they find is chiefly the *Endameba buccalis*. Secondary factors are possibly a diminution in individual resistance and chiefly a trauma to the gums with hard tooth brushes, floss, picking the teeth, etc. The morbid processes are described with the aid of many excellent drawings; the contagiousness of the disease (the common drinking cup is tabooed even in the home); the symptomatology, bleeding from the gums being probably the earliest symptom; the diagnosis, including a detailed description of the technique of examining for the specific organism; and finally the treatment and the prophylaxis. In a full discussion of the treatment the authors state that they have found that in a large percentage of cases ipecac given in suitable dosage by mouth causes the disappearance of endamebæ about as quickly as emetine given hypodermically. This book will repay reading by the general practitioner.

Society Reports.

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-second Annual Meeting, Held in San Francisco, June 18 and 19, 1915.

THE PRESIDENT, DR. HENRY SEWALL OF DENVER IN THE CHAIR.

Friday, June 18—First Day.

President's Address.—Dr. HENRY SEWALL of Denver delivered this address in which he said that the scheme conceived by the founders of the society to bring together a band of workers who should systematically investigate physical forces of nature as they influenced the physiological reactions of the body did not seem to be sufficient to maintain the enthusiasm of the organization, and hence it had extended its scope to embrace practically all conceivable disorders of the human frame. After dwelling on the importance of the external environment reaction in its relation to the welfare of our minds and bodies, the speaker said there was an internal environment which came definitely with the spirit and scope originally marked out for the activities of the society, namely food and its metabolism. If it were necessary to banish from the medical curriculum every subject but one, he suspected that their practical usefulness as physicians would best be conserved if that one subject were dietetics. The meaningless and tiresome aspect which this subject had always presented had been utterly transformed in the light of the recent conceptions of intermediary metabolism, and especially of the still mysterious activities involved in the reactions of anaphylaxis. They had learned that the extraordinary manifestations of idiosyncrasy to foods and drugs were only extreme illustrations of forces common to them all. Disorder of metabolism which transformed the analysis of the most expert pharmacologist could yet often be foreshadowed or diagnosed by the every-day practitioner who but made the simple test for the presence of acetone in the urine. Acidosis, whatever its origin, was an expression of a pathological condition which it behooved the clinician to recognize, for it showed the presence of a criminal agent in the peaceful community of cells. The practitioner who would make routine tests for acetone in the urine of his patients might see many obscure conditions illuminated to the improvement of his therapeutic aim. From reports in the medical press it seemed that there was an epidemicity in the condition of acidosis which deserved definite investigation in order to determine the factors, seasonal, climatic, dietetic, or biologic, involved in its occurrence. The scientific study of diet had scarcely begun. Medical teaching on the subject of dietetics was lamentably deficient. A review of the medical literature showed very little on the subject of acidosis and that only in connection with diabetes mellitus. Here lay a rich field fallow to their plow. In speaking of the objects of the society, Dr. Sewall pointed out that their ideal should be not only happy social intercourse and intellectual uplift, but that the influence of each member should radiate far beyond the bounds of his personal activity. He should be productive. A very happy criterion of the fitness for publication of any piece of work was to be found in the query, "Does it advance medical science?" The enormous output of pathological, bacteriological, immunological, and pharmacological research had supplied them with a therapeutic armamentarium of a complexity which no man understood. This made judgment difficult. Although it was justifiable, nay imperative, that they should daily resort to the use of remedial measures of whose agents and reactions they were profoundly ignorant, nevertheless critical judgment was never to be deleted. The selfsame therapeusis might in the one case be the choice of a master and in the other of a fool. They had been reared in the teaching that to help Nature should be the guiding motto of the doctor's practice. It was not always realized that Nature held as dear the pathogenic germ as the higher organism which it invaded. As physicians they must realize that their human endeavors were simply a modern addendum to the eternal forces of evolution. In evolution there was coordinate transformation of the mental and moral with the physical attributes of man, and the practising physician must be a mind doctor and in the end his chief service was to comfort. In conclusion Dr. Sewall said that no organization was likely to duplicate the task which was theirs and expressed the opinion that it might be an advantage to appoint each year special committees for the consideration of definite subjects, such as, the alleged radioactivity properties of natural waters; the relation of the physical and chemical properties of the air in ventilation; the relations of immune sera and vaccines in the treatment of bacterial infections; the relative value of sensitized and non-sensitized bacteria in the treatment and prophylaxis, and many other themes in which they all were interested.

The Importance of the Personal Equation in the Treatment of Tuberculosis.—Dr. WILL HOWARD SWAN of Colorado Springs presented this paper, which was read by Dr. G. W. Holden of Denver. He stated that while not questioning in the least the importance of exact knowledge as to the pathology, bacteriology, and scientific data that might be available now or later, he wished to state what was evident in a body like this, that until a specific agent for treating tuberculosis was discovered, their chief aim must be to raise the resistance of the individual to the disease. They must study and treat the individual who had tuberculosis rather than the disease itself. The fact of the very infrequent incidence of tuberculosis in Colorado and other health resorts where there was an unusually large proportion of tuberculous population was good proof of the reality of acquired personal resistance. Resistance might be influenced by many factors in the person's physical, nervous, mental, and moral make-up; by his circumstances as to proper living and by his adjustment to and viewpoint of his environment, and much study was often necessary to get at the real situation. In many cases one's success would be in proportion to the care and accuracy with which this was done. Among the factors overlooked were coexistent disease and lack of sufficient food when it was supposed that the patient was getting enough. The recognition of the importance of obscure focal infections in the causation of various systemic and general diseases had brought help to some of the victims of tuberculosis and similar relief had been brought about by the removal of diseased tonsils or the cure of accessory sinus disease. It was quite certain that they often failed to appreciate how frequently weakened resistance was caused by lowered nervous and mental tone due to fatigue, grief, discontent, homesickness, and unhappiness from whatever source. The writer cited a number of cases in which these factors had played the decisive part in the progress made by the patient. Worry in any shape might do much harm. In looking over the histories of 740 cases of tuberculosis treated during the past fifteen years, 129 showed reason for believing that some form of nervous depression was at least an important causative factor, and he felt sure that it was much more commonly a cause than these figures indicated because some of the earlier histories gave no data on this point. The prolonged physical and mental rest, and the limitations necessarily imposed during a "cure" sometimes became so irksome as to be a real detriment to the patient. In such cases finding out and making available suitable mental diversion might be the means of changing failure into success. These considerations showed the need of personally taking case histories and getting into close confidence with the patient, in order that one might know all the factors in their lives which had to do with their powers of resistance. They also emphasized the need of treating the patient from the standpoint of the individual. (See also p. 562.)

Dr. J. N. HALL of Denver said the remark had been made in the paper that some patients did badly because they were not digesting their food. He had so often found than an associated appendicitis was the cause of failure to properly digest the necessary amount of food that he sometimes thought perhaps he had laid too much stress on this possibility. He thought at one time that the trouble was that these tuberculous patients had tuberculous appendicitis, but he had found that it was only ordinary appendicitis and such patients never did well until the appendix was removed. In an ordinary case of tuberculosis complicated by appendicitis it was worth while taking the risk of the operation in order to get the improved digestion which usually followed the relief of the appendiceal condition.

Dr. PHILIP KING BROWN of San Francisco said that it had been their experience at the Areouipa Sanatorium that about 10 per cent. of the patients had to have attention directed to the digestive function, and about five per cent. had to have the operation of appendectomy either considered or the appendix actually removed, and it was their practice to take as conserva-

tive a position as possible. The operation of appendectomy since it could not be done under gas anesthesia did not present such a serious problem for the tuberculous patient as formerly. In these tuberculous patients the condition of the teeth and tonsils should also be considered, and operation performed if required. In only one instance had they found a tuberculous appendix at operation. However, he believed that they should be conservative in reference to operative intervention.

Dr. W. J. BARLOW of Los Angeles pointed out that individualization which had been taken as the keynote of treatment by the author of the paper was much easier to carry out in the home than in a sanatorium. He had found that too much exercise on the part of a patient who should have been at rest might interfere with digestion, and that as soon as the patient took the proper amount of rest the digestion improved. As late as five years ago he had hesitated to operate for appendicitis on a patient suffering with tuberculosis, but he had found that these patients passed through the operation as well as a normal person. The psychological factor in tuberculosis cases was always interesting, and he felt that it was very important in every case.

Dr. JOHN M. SWAN of Rochester, N. Y., said the most important point in the paper was the emphasis placed on the importance of securing a proper mental attitude on the part of the patient, and this was not only true of tuberculosis but of every other disease. The physician was apt to expend so much energy in reaching a diagnosis in a case of tuberculosis that he had little energy left to work out the details of the case. It was the duty of the physician to help the patient adapt himself to circumstances, and this often required considerable psychical treatment.

Col. GEORGE E. BUSHNELL, U. S. A., of Fort Bayard, N. M., said it was not so easy to individualize in treating tuberculous patients in the army as in civil life. Their ideal in reference to diet need not necessarily be to get as much weight as possible but to get the patient into good condition so that he digested his food better, has perfect health and perfect metabolism. A patient might sometimes gain in weight and yet be doing badly.

Dr. G. W. HOLDEN, in closing the discussion, spoke further of the importance of the mental attitude of the patient and said it was frequently very difficult to control parents and relative of the patient who persisted in relating or writing the family troubles, financial and otherwise, to the patient. The diet of the patient also required individualization; sometimes the proteins had to be cut down and sometimes the starches, but where there were a large number of patients it was sometimes difficult to carry out the details of the diet.

Coccoidal Granuloma.—Dr. PHILIP KING BROWN presented this patient who had scalp lesions due to the coccoidal organism. The other symptoms and signs which the patient exhibited were those typical of pulmonary tuberculosis. Dr. Brown said the condition was very rare in California, though Dr. Dixon had a report of nine cases which he would present at the Pan American Congress. The lesions were somewhat like those of pellagra. It had been said that no case of coccoidal infection had been known to recover with the exception of one in which ankle was involved and prompt surgical intervention had prevented the extension of the infection. The lung symptoms were typical of tuberculosis, and the condition was not recognized until bacteriological examination revealed the nature of the infection.

Exhibition of Some Unusual Aneurysms.—Dr. PHILIP KING BROWN presented a specimen of dissecting aneurysm and gave a brief history of four cases. They were all aneurysms of the descending arch of the aorta, and in each case symptoms were present but no signs, the diagnosis having been made by the assistance of the *x*-ray.

Dr. DIXON of Leland Stanford University, said that the types of coccoidal disease were classified according to their primary lesion. Dr. Brown had spoken of one case that recovered and he also knew of one recovery. In this instance a resection of the elbow was done and a diagnosis of the condition was made after the operation, but not before. He outlined the history of another case in which a diagnosis of carcinoma of the stomach had been made. The patient died of bronchopneumonia, and after death the coccoidal bodies were found. There were findings in this case similar to those in a healed case of tuberculosis. Dr. Dixon exhibited frozen specimens and fresh cultures of the organism and also a number of specimens showing the close resemblance between the lesions of coccoidal granuloma and those of tuberculosis. Some of the cultures showed the spores, and it seemed that infection could not take place unless spores were injected. Dr. Dixon agreed with Dr. Brown that probably a large number of these cases were not diagnosed. The test for these organisms should be made in every case of clinical tuberculosis in which the tubercle bacillus could not be found.

Dr. CUMMINS of San Francisco, said he had seen a number of these cases and had studied them clinically and histologically, and it was interesting to compare them with blastomycosis. He described a case in which the patient appeared to have typhoid fever. At autopsy the gross findings appeared to be those of miliary tuberculosis, but the coccoidal organism was found and the lesions involved the lungs, spleen, liver, adrenals and kidneys. In another case the organism was found in lesions in the occipital and temporal bones, the scalp, dura, sternum, third, fourth, and fifth lumbar vertebrae, and the different viscera were involved. In another case an abscess over the left kidney showed the organisms of this disease. They must take cognizance of the fact that there were more cases of this disease in this part of the country than were being recognized. With reference to the difference between a coccoidal infection and blastomycosis a recent article in the *Journal of the American Medical Association* would clear up the uncertainty in the minds of many in regard to the difference of these two conditions.

Observations on the Blood Pressure in Cases of Dysthyroidism.—Dr. JOHN M. SWAN of Rochester, N. Y., presented this paper setting forth the results of his observations in fifty cases of dysthyroidism of varying degrees of intensity. The cases were analyzed with reference to systolic blood pressure, diastolic blood pressure, and pulse pressure. He had also studied the various factors concerned in determining the functional capacity of the heart as described in the paper which he presented at the 1914 meeting of the Climatological Association. In the cases in which the systolic pressure was higher than normal, the pulse pressure was above 40 in all. The cardiac efficiency factor was above normal in thirteen out of fourteen cases, being about 35 per cent. The percentage of the pulse pressure formed by the second phase was below 40, or could not be determined in ten out of 14 cases. It appeared to be the rule that in a case in which a high systolic pressure was determined at the first examination, such organic changes had taken place in the heart, kidneys, or arterial system that it was impossible to restore a normal condition to the circulation. The writer also included the report of a case in which he had made observations with reference to the alterations in blood pressure during and after hemithyroidectomy. Observations were made every five minutes during the operation, and after the operation other observations were made at varying intervals for several weeks. From a study of these cases it seemed legitimate to conclude that the first effect of dysthyroidism on the blood pressure was a lowering of the systolic pressure. This was accompanied by a disturbance in the pulse pressure, usually an increase. After the case had persisted for a varying period the systolic blood pressure began to rise, and after the development of cardiac hypertrophy and renal and vascular changes, the cases were converted into typical examples of chronic hypertension. The study of the various functional myocardial tests would seem to show that the myocardium was disturbed in nearly all cases, whether or not there was clinical evidence of such disturbance. During the operation of hemithyroidectomy in one case there was a sharp fall of systolic and pulse pressure and a rise in diastolic pressure. After the operation the systolic pressure again arose to a high point; but after the use of sodium nitrite it returned to a more nearly normal figure.

Dr. HENRY SEWALL of Denver said that many of their theories held well in the test tube, but clinically would not hold water. There was no subject so apparently simple as that of blood pressure, yet it presented many puzzling questions. It seemed that all the affairs of blood pressure in man had been determined before he assumed the erect posture, and it was difficult to explain the return circulation from the lower extremities on their theories of blood pressure. The physiologists were making extracts of various organs and all seemed to have a depressor effect. Howell said

that there was kinase in every living tissue and maybe it had something to do with blood pressure. All these things made the subject a very complicated one. Dr. Sewall asked Dr. Swan whether by the term dysthyroidism he meant hyper- or hypothyroidism, of what time he took the reading and whether the position of the body had much to do with the perception of the sounds.

Dr. JOHN A. LICHTY of Pittsburgh said there were several points brought out in the paper that were in accord with his experience, and yet he could scarcely reach the same conclusions as to the effect of operation on blood pressure. For instance, the operation of hysterectomy might be accompanied by a high blood pressure, and yet after a year or so the blood pressure would swing back to its usual condition. Another peculiar phenomenon was that frequently at the first consultation the blood pressure would be found high, but after the patient became acquainted with the new physician and the new régime the blood pressure would be found to be different and lower. So it seemed that it was distinctly dangerous to draw definite conclusions. The line that Dr. Swan had been observing was a very promising one, but the blood pressure should be watched in many more operations before coming to conclusions.

Dr. W. JARVIS BARLOW of Los Angeles confirmed what had been said with reference to finding a high blood pressure on first examining a patient and finding that it came down later when the patient had gained confidence. It seemed to him that the pressure findings in the operation on the thyroid were not necessarily due to operation on the thyroid, but might be found to be similar in other operations. In regard to dysthyroidism and high blood pressure, it seemed to him that the high blood pressure was due to secondary cardiovascular changes rather than primarily to the dysthyroidism.

Dr. JOHN M. SWAN of Rochester, N. Y., said that for the past three years he had been living in a thyroid country and he noticed many women with pyramidal necks indicative of thyroid abnormality, and had thus been led to make a study of this condition. He had come to the conclusion that there was no such a thing as separating hyper- from hypo-thyroidism. These conditions bore the same relation to each other as tuberculosis did to consumption. A patient was said to have tuberculosis for many years before he was said to have consumption, and the same analogy might be applied to thyroid disease, so it seemed to him that the better name was dysthroidism, though the term "thyroisis" had been suggested. With reference to the question of reading the diastolic pressure, he had had no trouble with it. He read the manometer when the sounds had disappeared. There were two methods of reading. As the blood pressure fell there was first a tap, then a murmur, and then the murmur disappeared and the tap came back. There was a point at which the tap became muffled and then disappeared altogether. Warthin said they should read when the sharp tap became muffled and others said one should read when it disappeared entirely. In his readings he took the point where the tap disappeared entirely, and he found difficulty in making it out. The study was made systematically and the conditions were the same in every observation. The patients were in recumbent position and the cuff was placed on the bare arm. Dr. Swan said he was glad Dr. Lichty had spoken of the effects of other operations on high blood pressure; he had been able to find nothing on the subject in the literature. The question as to the part played in the fluctuations of blood pressure by the results of the ether, of the operations *per se* or of both was an interesting query. Perhaps in the operation of hemithyroidectomy observed the handling of the thyroid and the possibly squeezing some of the secretion into the circulation might have had something to do with the changes in the blood pressure. In regard to Dr. Barlow's remark that the high blood pressure might be due to the secondary cardiovascular changes, his study had convinced him that the tendency of dysthyroidism was to produce a high blood pressure. He had been observing cardiovascular disease in women of the better class where infection and the excesses of tobacco and alcohol could be excluded and he had found evidences of thyroid disease that had been coming on slowly for years, so that its effects on the cardiovascular system were similar to those produced by alcohol, tobacco and other excesses.

The Physician and the Weather Bureau.—Dr. FORD A. CARPENTER of the United States Weather Bureau of Los Angeles, Cal., presented this paper, which he illustrated by lantern slides. He stated that the relation between climate and health had been recognized for at least 2,000 years. He quoted to show that Hippocrates recognized this relation. The object of his paper was to suggest means by which the medical profession might utilize the vast storehouse of climatic data accessible at Washington and at all Weather Bureau stations, to prove the readiness of the personnel of the Bureau to assist the physician to present some applications of these data from a layman's standpoint, and to offer an account of some intensive climatic studies which had been presented by the writer during the past few years. The Weather Bureau presented facts and not the ordinary health resort advertising literature. The source of the data was from the regular stations of the Bureau and from special cooperative stations. There were about 200 regular stations and about 4,000 cooperative stations scattered over the United States. The regular stations were about one to 15,000 square miles of territory. In the number of stations of all kinds California took the lead with 511 meteorological stations. Such stations were equipped with barometers, thermometers, wind-vanes, rain and snow gauges and anemometers and nearly all had sunshine records, barographs, thermographs, and other apparatus in which a continuous automatic record of the local weather conditions was registered. At each of the stations was one or more trained observers. The weather map might be most useful to the physician who kept track of the storm movements and gathered first hand information as to existing and coming weather conditions over the United States. He would soon learn to associate stormy, cloudy, and comparatively warm weather with those atmospheric whirls called "lows," and fair, sparkling, comparatively cool weather with the whirls called "highs." The indications of the weather map found many applications. For instance, one of the large California citrus fruit growers timed the shipment of his oranges so that they would have the advantage of the cool, dry weather of the weather maps "highs" in their eastern journey. There was no reason why a physician should not do likewise and by taking advantage of the weather map and advise his patient when they might travel so as to avoid deleterious weather conditions. Observations at many places were necessary before the climatology of the United States could be properly studied, and this had given rise to the Climatological Service of the Bureau. The centers of this service collected temperature and precipitation observations from more than 4,000 cooperative and other stations and published each a monthly and an annual summary, giving a large amount of climatological data for each month and for the year. The writer recommended to physicians one of the bulletins prepared by their scientific staff entitled "Climatology in the United States," which was to be found in the station library of any Weather Bureau office. In addition to placing these records at the disposal of the applicant, the Weather Bureau officials would be prompt and courteous in receiving applicants for data whether it be in person or by correspondence. There was considerable misconception regarding the relationship between air pressure and health. The mere change of atmospheric pressure from day to day had nothing whatever to do with one's physical well-being. A recent publication stated that when the barometer dropped from 30 to 29 inches the human body was relieved of half a ton of pressure with resulting effects on the physical organism. In the first place it was unusual for the barometer to drop one inch in so short a time, and in the second place observations had proven that the influence upon the body of variations in pressure were greatly overestimated. It was rather the fair weather and decreased humidity which accompanied a rising barometeric pressure that elevated one's spirits or the cloudy threatening weather and increased humidity which accompanied a falling barometer that affected the human system. The location of home, office or workroom had more to do with the health of the occupant than whether the relative humidity was much above or below the normal. Exposure to sunshine and ample ventilation were all-important. Facing houses with relation to natural air drainage was also most important in selecting a home. Many a home otherwise healthful and satisfactory had been abandoned because the architect or owner did not consider the principles laid down by Hippocrates 2,000 years ago. The author suggested other opportunities for the study of health in

its relation to climate in the light of augmented data, such as the proper selection of sanitarium sites, sensible temperature (wet bulb thermometer readings) and infant mortality, acute infectious diseases and sunlight, using the sunlight charts of the Weather Bureau. He also described an extensive series of observations being made in Southern California with a view to extensive citrus fruit culture, where 16,000 acres of land at various elevations from 100 to 1,300 feet were being intensively studied and it was believed to be possible to chart every ten acre plot. It was very surprising to observe the effect on citrus culture of seemingly slight variations in altitude and situation of the land. He also compared Los Angeles and Riverside. The former, 10 miles from the sea, showed a lower range of temperature and higher relative humidity than the latter which was 55 miles further east towards the desert and illustrated most clearly the influence of the desert upon temperature and low humidity, and above all its remarkably regular oscillations. In closing the speaker expressed the opinion of an eminent California physician to the effect that if physicians would go into this subject and study it in conjunction with the weather bureau that the State could be plotted so that the real atmospheric conditions of all localities and their effect upon the functions of the body would be known. But that altitude, temperature, humidity, prevailing and unusual winds had much effect upon many individuals there was no doubt. This subject should be worked out by the Weather Bureau and the medical profession. In response to a number of questions, he explained the ordinary day to day fluctuations of temperature in accordance with the well-known laws governing gas pressure. He discussed the question as to whether climates were changing as alleged by some and said that the records showed that no such changes were taking place. There was nothing more unreliable than popular statements on this subject. They were better equipped against the extremes of temperature than formerly. There was no evidence to show that irrigation caused any climatic changes whatever, or that the use of high explosives had any influence in producing condensation of moisture and rain. The personal equation was a very uncertain factor in taking the readings of the various instruments employed to record temperature, humidity, etc., and hence the instruments of the weather bureau made all these readings automatically and their accuracy was to be depended upon.

Lung Involvement Secondary to Suppurative Abdominal Disease.—Dr. J. N. HALL of Denver read this paper in which he declared that the frequency of subphrenic abscess was probably not appreciated by the majority of practitioners; certainly the less common instances in which a suppurative process burrowed through the diaphragm, and gave rise either to empyema or to perforation into a bronchus or the pericardium were frequently overlooked. An ascending infection from a suppurating rectocecal appendicitis was a common cause of sub-phrenic abscess. The author had reported nine cases in a series of 500 cases of appendicitis and this probably did not overstate the frequency of the complication. Diffuse subphrenic suppuration was much less often found in this type than in any of the others. Gastric and duodenal ulcers frequently caused subphrenic abscesses, but these rarely perforated the disphragm. With this condition in amebic dysentery there was frequent involvement of the pleura and lung with infrequent subphrenic abscess. Left-sided subphrenic abscess usually originated from ulcer, although suppurative appendicitis, acute pancreatitis, suppurative cholecystitis, and amebic liver abscess might be the starting point. The mere presence of subphrenic abscess must not be taken to establish its abdominal origin. Dr. Thomas H. Hawkins had reported one case in which an abscess resulting from a suppurative salpingitis finally evacuated through the lung. Archibald's figures indicated that about four per cent of cases of subphrenic abscess originated from the intrathoracic infection. The lymphatic distribution was such that the invasion from the abdomen was vastly more frequent; the right pleura and lung were therefore involved much more frequetly than the left. Appendicitis and suppurative involvement of the right lob of the liver caused most of the instances of subphrenic suppuration which brought about the involvement of the respiratory tract. Yet it was possible that the spread of the process beneath the diaphragm might cause involvement of the pleura on the side opposite the original abdominal affection. The most frequently found bacterial infection in subphrenic abscess was that of the colon bacillus. The diagnosis of subphrenic abscess often depended upon the recognition of some possible cause in the abdomen. In empyema, unless it was entirely evident that the affection followed immediately after acute pneumonia or broncho-pneumonia, the history should be taken with special care to overlook no evidence of prior abdominal disease. When one had obtained a history of appendicitis, amebic dysentery, gallbladder disease, or other similar affection, and symptoms such as irregular fever, irregular chills, sweats, leucocytosis, perhaps cough, dyspnea, pain, and even in neglected cases bulging, redness, and edema of the chest, he could feel quite certain that he was dealing with subphrenic abscess. The heart might be displaced to the opposite side. Tenderness and deep pain and discomfort were common. The diaphragmatic movements were abolished. Pushing downward of the liver in right side involvement, or of the spleen upon the left side, should be noted. Muscular rigidity below the costal arch was probably always present. The higher line of dullness over the liver and pushing upward of the diaphragm behind suggestive of pleural effusion were reliable evidence of the presence of an abscess. The *x*-ray plate demonstrated the shadow of the effusion and might prove it to be subdiaphragmatic in location. The fluoroscope revealed the absence of respiratory excursion of the diaphragm. Feeble respiratory sounds, a lessened vesicular murmur and even slight dullness might be detected. Pleural friction was occasionally to be heard, less frequently pericardial friction. Splashing was decidedly less frequent in pyopneumothorax subphrenicus than in the usual form above the diaphragm. Increased area of dullness in the lateral region of the chest was to be found if the abscess was of much size. The displacement of liver dullness by tympany if gas was present was of extreme importance in diagnosis, and was usually associated with movable dulness. Subphrenic abscess rarely broke externally. In one of the writer's cases it broke into the colon with fatal results. Given such a history and some of the findings described and they were ready to consider the possible invasion of the region above the diaphragm. This probably occurred in 25 to 35 per cent. of the neglected cases. It was more frequent in extraperitoneal type than in the intraperitoneal abscesses. The general symptoms after pleural involvement were much the same as those of subphrenic abscess. If in doubt as to subphrenic absces or pleural effusion the needle must be used freely, the patient being prepared for operation, and in serious cases an anesthetic should be used. The greater danger of using an exploring needle on the left side and the need of emptying the stomach by means of the tube before aspiration, should be borne in mind. One was likely to be satisfied if he found one kind of fluid in one place in the aspiration of the chest, hence it was well to recall that when effusion above the diaphragm existed with subphrenic abscess, the latter was too frequently overlooked. Acland stated that in case of doubt, clubbing of the nails pointed quite definitely to the supradiaphragmatic location to the disease. There were notable features in the amebic hepato-pulmonary abscess. Extensive destruction of lung tissue was not infrequent, and expectoration of the products of tissue diintegration might be noted. In case of perforation into the lung death might occur from the pneumonic process, from abscess, or from gangrene before the abscess emptied itself through the bronchus. In fact the latter process was probably a function of the milder infections only. The most striking phenomenon in the whole general process was the sudden breaking through of the abscess into the bronchus, with expectoration, of foul pus. Pulmonary embolism was spoken of as a complication of subphrenic abscess, coming from the thrombotic process in the veins of the abdomen, but a much more striking variety of embolism might occur in the cases of perforation of the lung by the subphrenic abscess. One of the author's cases described elsewhere had septic embolism of the popliteal artery, survived amputation, and suffered two other embolic attacks. The source was evidently the thrombosis in the branches of the pulmonic vein around a large cavity demonstrated in the lower right lobe. There were rare instances in which the abscess ruptured into the pericardium. Pericardial friction and even splashing might be noted. This complication was of extreme gravity. In cases of subphrenic abscess with lung involvement complete recovery was most exceptional. Yet the author could not agree with Rolleston's statement that death commonly resulted in two or three months, since he had had three patients who had lived from one to ten years, and two of

them were alive when lost track of. The prognosis was so grave that early diagnosis must be followed by prompt operation even at considerable risk. Empyema must be thoroughly drained to avoid the danger of lung involvement; after this occurred surgery rarely offered any assistance.

Dr. Henry Sewall spoke of the difficulties encountered in making a diagnosis of subphrenic abscess and said he would have to confess to having made many miscalculations in diagnosing the condition. He believed it was overlooked ninety-nine times where it was recognized once.

Dr. John A. Lichty of Pittsburgh said his experience has been somewhat different from that of Dr. Hall. In about 700 cases of appendicitis he had not found subphrenic abscess more than five or six times and in only one instance did he find an empyema and that ruptured into the lung.

Dr. Philip King Brown of San Francisco said he had just had an experience with two cases that answered this question. One had been operated on for a paranephretic abscess and had a streptococcic septicemia and pleurisy, and very striking friction râles were perceptible. The other was a deep abscess of the liver which was accompanied by a pleurisy on that side of the lung. Bevan had pointed out that in acute appendicitis pleurisy of the lower right portion of the lung was not uncommon, though there was no lymphatic connection to explain the association of the two conditions.

Dr. Hall, in closing the discussion, explained that the reason he had found these subphrenic abscesses more frequently than some others was because of the fact that he lived in a more sparsely settled country where it was improbable that a person suffering with such a condition would find a physician who would be able to make the diagnosis. Another reason for finding the condition more frequently was that patients were not so likely to be operated on early for the conditions that might produce subphrenic abscess if neglected. He related that three cases seen in succession in which the subphrenic abscess was due to appendicitis all had deep cavities just above the diaphragm; these were of the neglected type and one would not see them in a large city. That was the reason he had insisted on early operation because ninety-nine per cent. of the trouble was due to neglect and showed what an neglected appendicitis could do. In reply to the question as to whether these abscesses perforated more frequently than empyema, Dr. Hall said he thought the subphrenic abscesses perforated oftener than empyema because empyema was more likely to be recognized and treated.

The Acute Infections in Diabetes Mellitus.—Dr. John A. Lichty of Pittsburgh, Pa., presented this communication. He stated that from the beginning of their knowledge of diabetes mellitus as a clinical entity, it had generally been recognized that patients suffering from this malady were poor surgical risks and many theories had been advanced to account for this fact. One of these theories was that there was a disturbance of tissue vitality due to the existing hyperglycemia and on account of this disturbance bacterial invasion occurred more easily. This view had been largely substantiated by Dr. J. C. DaCosta and Dr. E. J. G. Beardsley in the clinical laboratory of the Jefferson Medical College Hospital. There was very little in the literature, however, that would lead one to think that the ordinary infections which were included under medical diseases were particularly fatal in patients having diabetes mellitus, with perhaps the exception of erysipelas, lobar pneumonia, and pulmonary tuberculosis. It was the author's purpose to show that the more simple and ordinary infections were not infrequently a determining factor in influencing the mortality of diabetes. The writer reported two cases of diabetes in the first of which an acute infection of the nasopharyngeal mucous membrane was followed by an acute otitis, and in the second a cold in the head was the starting point of a train of symptoms which speedily led to a fatal termination. He said he might mention other instances of similar apparently mild infections and some of the graver infections, such as lobar pneumonia and acute pulmonary tuberculosis, but they all showed the same rapidly fatal results. It was found that when the restricted carbohydrate diet upon which the patient usually maintained his weight and feeling of well being was relaxed and an attempt made to force upon him a large amount of general diet, as was usually done in pulmonary tuberculosis, the amount of sugar eliminated invariably increased and the chest signs became rapidly alarming. On the other hand, if the urine could be kept sugar free or nearly so and the caloric value of the diet could be maintained at the normal or slightly above the normal requirements, other things being equal the patient invariably improved. This observation has been made so often that it had led the writer to apply the same principle in the treatment of the acute infections in diabetes mellitus. That was, no matter how grave or apparently trivial the infection might be, the consideration of the diabetic element in the case was of paramount and extreme importance. Of 33 fatal cases of the writer's own series, eight died of some acute infection. This included cases of pulmonary tuberculosis and lobar pneumonia. Statistics which the author had collected from Joslin Janeway, and Friedenwald showed that about one-third of all the deaths were either directly due to or hastened by the acute infections. This fact should lead one to warn his patients suffering from diabetes mellitus against the dangers of infections, and to instruct them properly in prophylactic measures. It also suggested the necessity of extreme care in treating these cases even though the infection seemed the mildest and most innocent.

Dr. F. M. Pottenger said he had had the same experience as the writer of the paper in diabetes mellitus in tuberculous patients. He had found that about one-half the patients on an ordinary diet lost their sugar temporarily or for a period of months. He related the instance of one patient who had been sugar free for some time who after being struck by a croquet ball was completely unnerved and the sugar promptly appeared, though the man had been free from sugar for a long time on a regular diet.

Dr. John A. Lichty of Pittsburgh said that the treatment of the diabetic and the tuberculous patient were very much alike except that the diabetic could not take the same amount of carbohydrate. If the tuberculous patient was fed on fats and proteins with restricted carbohydrates the pulmonary lesion would heal as readily. It was necessary to treat acute infections with a great deal of consideration and care.

A Case of Primary Pulmonary Aspergillosis.—Dr. G. W. Holden reported this case, which was originally diagnosed and unsuccessfully treated as pulmonary tuberculosis, and later tentatively diagnosed as Hodgkin's disease. Only a comparatively few instances of aspergillosis in human beings had been reported, and most of these had occurred in France among pigeon feeders and those who handle grain and flour. Sporadic cases, however, had been reported from other countries. The fungi pathogenic for man had been divided by Plaut into three groups according to their pathogenic effects: (1) Moulds in the narrowest sense (mucor and aspergillus), (2) the fungus of thrush, and (3) the fungi infecting the skin. Still divided the genus aspergillus into six species, and of these the form most pathogenic for man was aspergillus fumigatus. It was very frequently observed in the lower animals and in birds, in which it often produced a psuedo tuberculosis and it was supposed that the infection might be carried from birds to man. Aspergillus fumigatus was found most frequently in the ears, nose, and mouth. In the lungs it was thought to be secondary to an already existing tuberculosis until Dieulafoy and others reported cases of primary infection about 1890. A sufficient number of authentic cases had been observed to make it worthy of consideration in diagnosing obscure cases of pulmonary tuberculosis. Pulmonary aspergillosis might be either acute or chronic; when acute it resembled bronchopneumonia, and when chronic the symptoms were similar to those of pulmonary tuberculosis. The recognition of the disease depended upon finding the parasite in the sputum. When stained the parasite appeared in the form of myceleal threads with spores scattered in and around. The case reported occurred in a woman 47 years of age who had never been robust, and gave a history of bronchitis recurring every winter since she was 16 years of age. She had been sent from her home in western Pennsylvania to Colorado on the supposition that she was suffering from pulmonary tuberculosis. The right and left cervical and axillary glands were enlarged from the size of a hickory nut to that of a small egg. They were freely movable under the skin. As expectoration was scant no specimen was obtained at first. Later a specimen showed opaque white masses containing a few epithelial and a few pus cells, but no tubercle bacilli. The microscopic finding showed a few diplococci and mycelia. The sputum was cultured and a pure culture of aspergillus found. Other cultures showed the same findings. Dr. Anna Williams and Dr. Gurley of the New York Board of Health Labo-

ratories on their first examination classified the organism as a. fumigatus and later as a. nidulans. The patient lived fifty-four days after entering the sanatorium and the course of the disease was that of chronic pulmonary tuberculosis with scant expectoration containing but few pus cells. At no time was there any hemorrhage or blood stained sputum, as would be expected in aspergillosis. Evidences of pulmonary induration and contraction became more manifest as the disease progressed and there was increasing marasmus. Death was due to right sided dilatation of the heart. Post mortem was not permitted but the writer was allowed to remove one gland. There was no evidence of glandular structure. With the exception of a few small areas near the periphery filled with small round cells the entire parenchyma was replaced by dense fibrous tissue which in a few small places had become necrotic. Scattered throughout this fibrous tissue were numerous rather deeply stained bodies showing the characteristics of the aspergillus. The gland was cultured for the organism of Hodgkin's disease but the results were always negative.

Dr. CHARLES BROWNING of Los Angeles said he had seen two cases of actinomycosis and that his bacteriologist was on the lookout for it. He had also found a few cases of saccharomycosis. They were in the habit of making a systematic investigation for these organisms in cases of clinical tuberculosis in which the tubercle bacillus could not be found.

Dr. HENRY SEWALL of Denver said the finding of a fungus in making an examination of sputum was not extremely unusual and said such a finding should not lead one to the conclusion that he had found something new. It was known that if urine was kept for a time it would develop a fungus.

Saturday, June 19—Second Day.

Cardiac Syphilis; Its Incidence and Diagnosis.—Dr. J. M. ANDERS of Philadelphia presented this communication which was read by Dr. J. N. Hall of Denver. The writer stated that the common occurrence of syphilitic myocarditis, mesaortitis, angina pectoris, and aortic incompetency was now universally recognized. A statistical investigation into the question of the bearing of syphilis upon the incidence of these conditions had yielded significant results. The statistics of Longcope, Clifford Allbutt, Feissenger, Collins, and Babcock, of which he had made a collective investigation, embraced 219 cases; of these 133 or 60.7 per cent. were clearly due to lues. In a considerable number of the cases of aortic incompetency to be found in the literature no reference was made to a Wassermann test, so it was obvious that the figures underestimated the true rôle of syphilis in the production of this condition. Early diagnosis of aortic incompetency was of the utmost importance to the end that serious damage to the aortic segments might be obviated by intensive antisyphilitic treatment. In the absence of rheumatism, gout, lead, alcoholism, pyogenic infection, or a predisposing occupation, cases of aortic incompetency should be labelled suspects and given the benefit of vigorous antisyphilitic treatment. Special physical signs that aided in the establishment of the luetic character of the chronic valvulitis were enlargement of the left ventricle (and therefore capillary pulse and double sound over the crurales were not so marked) and a greater degree of arrhythmia. The cardiac lesions of syphilis usually appeared within two or three years after the infection and sometimes much earlier. The importance of the Wassermann reaction as a means of determining the etiological variety of the lesion should be emphasized. When myocardial syphilis developed in the secondary stage the onset was rapid or even acute and the principal features were irregularity of heart action, tachycardia, intermittence, extrasystole, and rarely soft murmurs, especially in the mitral area. The symptoms did not differ from myocarditis due to other acute infections. These symptoms might disappear after a few days as a result of energetic antisyphilitic treatment. This fact helped to emphasize the importance of early recognition of the condition. True angina pectoris might be associated with the myocarditis and angoid pains were not infrequently present. The Stokes-Adams syndrome was commonly caused by syphilitic myocarditis or fibroid change in the bundle of His. The writer had collected 270 cases of angina pectoris from the literature and only 26.5 per cent. gave evidence of syphilis. This was too low an estimate since there was no mention of the Wassermann test having been made. Every case of angina pectoris during the younger period of life was open to the suspicion of syphilitic origin. When either aortic regurgitation of syphilitic myocarditis of marked extent existed curative treatment was impossible of achievement as a rule, and hence the necessity of vigorous early and prolonged treatment. The Wassermann tests should be made until they were no longer positive. The treatment consisted of the alternate use of intramuscular injections of the salicylate of mercury and salvarsan. The iodides were reserved for later use after the active syphilitic process had been checked. In the later stages the use of salvarsan was quite justifiable in the opinion of the author in myocarditis and aortic insufficiently in which the actual condition of the myocardium was undeterminable but not degenerated to a marked degree and in those cases in which the patients urgently demanded that something be done.

Dr. JOHN M. SWAN of Rochester said that it was his experience that cardiac disease where there was no history of rheumatism or of other infectious disease was very often due to syphilis. This was especially apt to be true of physicians, who often had a syphilitic lesion without recognizing it. Dr. Swan related the case of a physician with a typical case of aortic regurgitation. After going over his history carefully it was found that he had probably been infected with syphilis while attending a labor case. According to the statement of Dr. Harlow Brooks cardiac irregularities often cleared up after the administration of the iodides, and he had seen several cases of ventricular extrasystole definitely disappear after the administration of the iodides. One should always suspect syphilis in these cases in which there was no other definite etiological factor.

Dr. JOHN A. LICHTY of Pittsburgh said that no one was more competent than Dr. Anders to speak on this subject, but there were several points he wished to call attention to. He had heard Dr. Collins read his paper in Washington eight years ago when the Wassermann test was comparatively new and he had followed the work of Dr. Harlow Brooks and there seemed to be no doubt that there were more cases of syphilitic aortitis than ever before, yet the point should not be overlooked that unless there was an autopsy one was not free to speak definitely about them. For all cases having a positive Wassermann were not necessarily due to syphilis. One should have the autopsy record with which to back up his statements. Dr. Lichty stated that he had had three cases that gave a positive Wassermann and aortic lesion and yet at autopsy he found an infective aortitis. In one case the infection was a streptococcus viridans, in another a tuberculous pericarditis, and in the third the streptococcus was found in the blood stream. In Pennsylvania they did not find the spirochete so frequently in heart lesions as Dr. Warthin had found them; this was probably due to a difference in the source of the material, since Dr. Warthin got most of his from an orphan asylum. It was well to point out the value of other clinical symptoms and not to permit the Wassermann reaction to have undue weight.

Dr. SWAN suggested that in the cases spoken of by Dr. Lichty there might be a possibility that the streptococcus infection was implanted on top of a syphilitic condition.

Dr. HENRY SEWALL said it always seemed to him that the syphilitic presented a psychic or nervous condition different from the normal individual and that this would have a definite effect on aortic trouble due to syphilis.

Dr. JAMES H. MCBRIDE of Pasadena, Cal., said he could not say definitely that there was a psychical deviation which could be attributed to syphilitic degeneration. One author had said that aortic aneurysm was always due to syphilis except in cases of injury, and he had seen several cases of heart lesions directly due to syphilis, but his experience was not extensive as was that of Dr. Anders.

Some of the Disputed Anatomicopathological Questions in Tuberculosis.—Dr. F. M. POTTENGER of Monrovia, Cal., presented this paper, in which he discussed first the subject of bovine and human tuberculous infection *versus* bovine and human clinical tuberculosis and gave his reasons for believing that the bovine tubercle bacilli after living in the human tissues for a time adapted themselves to the new conditions and gradually became the bacilli which would naturally be produced on the human soil—in other words, that the bovine bacilli underwent transmutation. With reference to the primary focus and metastases, the writer reviewed Gohn's position and stated that he took a point of view

slightly different, but one which could be harmonized with it. There was a marked difference in the behavior of the infection which took place in an animal or a human being who was healthy at the time of inoculation and one which was already infected. An infection when once present produced a hypersensibility of the cells and in this way created a defense against further infection by the same organisms. The mucous membrane and other tissues of the non-infected organism showed no specific defense and consequently offered little opposition to the passage of the bacilli. This was seen in the readiness with which bacilli passed through the tonsils of children and affected the cervical glands of the bronchi and the peribronchial glands, or through the intestines and affected the mesenteric glands. The first important barrier met prior to true infection was by the lymphatic glands which were particularly active in protecting the organisms at this time. After infection the cells became sensitized and a cellular defense became general. Then a specific opposition was offered to the bacilli at every point of entry. The metastases usually occurred through the blood and were produced as a rule by a few bacilli and the contact with the sensitized cells limited their virulence, the resulting lesion being abortive. Later it might become active and other metastases might occur. This theory would explain the freedom of the lymph glands from secondary metastases both in the larynx and in the intestinal tract. The essayist discussed the reasons why the apex of the lung was usually involved in the adult while any portion might be affected in the child, and attributed it to the anatomical changes incident to assuming the erect position and to the rapid growth, particularly at the time of puberty which retarded the motion of the apices of the lungs and thus favored retardation of the blood and lymph circulation. All of these factors favored the implantation of the tubercle bacilli at the apices of the lungs. In discussing the small heart in tuberculosis the writer stated that this small heart was found in early tuberculosis where the tissues had not had time to suffer degeneration and also in otherwise normal individuals, as well as in other abnormal conditions. The feature in common in all instances was the deficiency of the inspiratory act. The author then described the mechanism of inspiratory deficiency, showing how it was responsible for the production of the small heart. The condition of inspiratory deficiency was constant in tuberculosis and the heart was obliged to accommodate itself to the lessened output.

Appendicitis as a Complication of Pulmonary Tuberculosis.—Dr. HUGH M. KINGHORN of Saranac Lake presented this communication, in which he gave the results of a study of the frequency of appendicitis in 674 cases of well established pulmonary tuberculosis. Among these appendicitis occurred in 36 instances. The disease was slightly more prevalent in the male. Of these 36 cases 22 were operated upon and 14 recovered without operation. One death occurred from fulminating appendicitis within three days of the operation. Acute appendicitis in persons suffering from pulmonary tuberculosis should be treated as in a normal healthy person. Even feeble patients stood the operation well under nitrous oxide and oxygen. When the appendicitis was not acute and the patient was feeble the pulmonary disease should be considered.

Papers Read by Title.—Among the papers read by title were the following: "Addison's Disease and Tuberculosis," by Dr. Judson Daland of Philadelphia; "The Relation of the Spleen to Tuberculosis Infection," by Dr. William Charles White of Pittsburgh; "Eventration of the Diaphragm," by Dr. Morris Manges of New York City; Movable Mediastinum and the Manometer," by Dr. C. D. Parfitt of Gravenhirst, Ontario Canada; "The Effects of Some Drugs upon the Pulse Form in Man," by Dr. A. W. Hewlett of Ann Arbor, Mich.; "The Occurrence of Bright's Disease and Nephritis in the United States, with an Attempt to Trace the Influence of Humidity in Relation to the Mortality in Twenty-five Cities," by Dr. Guy Hinsdale of Hot Springs, Va.; "Remarks on the Treatment of Cardiopathies from the Standpoint of Physics," by Dr. I. M. Taylor of Philadelphia, Pa.; "Interesting Features of a Scarlet Fever Epidemic in Gaylord Farm Sanatorium," by Dr. David R. Lyman of Wallingford, Conn.

Election of Officers.—The following officers were elected to serve during the ensuing year: *President*, Dr. James Alexander Miller of New York; *First Vice-President*, Dr. Philip King Brown of San Francisco; *Second Vice-President*, Henry Martin Bracken of Minneapolis, Minn.; *Secretary, Treasurer, and Recorder*, Dr. Guy Hinsdale of Hot Springs, Va.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 5, 1915.

DR. CLARENCE A. MCWILLIAMS, IN THE CHAIR.

Exclusion of the Pylorus by the String Method.—Dr. V. GAUNDIANI presented this patient, upon whom he had operated last July for duodenal ulcer. After he had performed the posterior vertical gastroenterostomy the patient's condition was so poor that he thought to occlude the pylorus by the Paravecchie method as the quickest one. At the 1914 meeting of the German Surgical Society, Guleke of Strassburg reported thirteen cases, eleven of which had been examined for a period of time after this operatin, varying from six to twenty months. The results in this series of cases were more satisfactory than those obtained by any other method; in only one of these thirteen cases was the pylorus patent. Paravecchie emphasized in his papers that the ligature must be a string and not a thread. In the patient presented a string such as was used in obstetrics to tie the cord was passed one-half inch inside the pylorus, and tied gently, until an almost complete approximation of the mucosa was obtained. The knot was buried by seroserous stitches. The patient made a good recovery, gained afterward nearly thirty-five pounds, and could be regarded as completely cured. An *x*-ray plate taken one month ago showed the pylorus firmly closed. It seemed that this simple operation deserved to be better known by the surgeons and applied in all cases in which the classical Doyen-Eiselsberg method, owing to the condition of the patient, could jeopardize the result of the operation. One could say that, properly performed, it realized a perfect occlusion of the pylorus, at least for the period of time necessary to secure the healing of the ulcer.

Report of a Case of Intussusception with Resection.—Dr. EMERY MARVEL of Atlantic City, N. J., said that cases of intussusception in adults interested him. Intussusception in the adult was rare, and when present was usually occasioned by either a cicatrized ulcer or a neoplasm. He said he wished to cite a case coming under recent observation. An Italian laborer, thirty-seven years of age, was seized with intense pain in the abdomen associated with vomiting. At 6 A.M., January 22, 1915, he summoned a physician, who saw him at 9 o'clock and administered morphine. His associate, Dr. Andrews, saw the man at 2 o'clock and found him in intense agony, writhing with pain, unable to stay in bed, and clamoring for relief. Being informed that this pain had not let up since the onset in the morning, he believed a serious abdominal condition was present, and after an unsuccessful attempt to relieve the bowel by enema, a quarter of a grain of morphine was given hypodermically, and the necessity of an immediate operative treatment was advised. He saw the man two hours later, finding him still complaining of pain and tenderness over the abdomen; the wall was board-like and unyielding. The intense distress was located in the epigastrium. A suggestion of a gastric or duodenal ulcer was in his mind, although the man had little or no depression of the heart's action and showed no other evidence of shock. He was anesthetized at 4 o'clock, and so soon as his abdomen relaxed a tumor was visible in the left hypochondrium. An incision in the median line permitted the mass to be exposed with ease. This showed an intussusception of extreme dark color and evidently gangrenous. Tears in the serosa were observed in several places. It was impossible to reduce the intussusception. Resection was imperative, which was completed with end-to-end suturing. The abdomen was closed without drainage and a complete recovery followed. The man at this time was at work. Endeavoring to ascertain what had occasioned the intussusception, the specimen was opened and revealed small tumors of the mucosa of the bowel, one of which was at the point of intussusception, and was very evidently the cause of the bowel slipping and locking itself. There were four of these tumors in the resected bowel. The pathologist's report of these tumors showed them to be adematous polypi. Whether there were other tumors or not in the remaining bowel he could not say. He did not recognize the presence of these tumors at the time of operation. The resected bowel measured about seven feet when straightened out; it was over two feet in length upon the greater curve and was triplicated. The specimen was exhibited.

Severe Electric Burns.—Dr. S. M. MILLIKEN pre-

sented this patient, an electrician, admitted to the Lincoln Hospital after having received 11,000 volts of electricity. The burns covered the face, ears, anterior half of the neck, entire chest and abdomen (these being third-degree burns), right half of the back, left anterior axillary margin and front of the left shoulder (also of the third degree). The right arm and forearm had a third-degree burn, were enormously swollen and cadaveric in appearance and no signs of circulation could be found beyond the proximal part of the axillary artery. There was no sensation below the tip of the right shoulder. There were two areas of third-degree burns on the left arm on the flexor surface, each about the size of the palm of the hand. Similar third-degree burns were found on the left thigh and between the third and fourth toes of the left foot. After consultation with Dr. Peck and Dr. Lloyd, amputation was advised and refused by the patient and his relatives. In the hope that the vessels were constricted instead of thrombosed, relieving incisions were made from the point of the shoulder to the middle of the back of the hand. One was made through the cubital fossa, where the median basilic vein was cooked stiff. No sensation and no bleeding were encountered until deep fascia was divided in the forearm. The fascia was divided over almost the full length of the forearm. In an apparently unburned area one superficial vein was ligated and wet bicarbonate dressings were applied. The patient had been admitted to the hospital on June 16 and on June 26 the slough on the arm separating the extensor and flexor tendons were seen to be necrotic, the sheaths having sloughed off. The "cooked" area of the flexor muscles had sloughed and there was a deep slough over the first phalanx of the middle finger. On June 29 there was free bleeding from the right hand, and the digital artery on the ulnar side was found to have sloughed through and this was ligated. The patient had been running a temperature of 103° to 104.5° F. during the months and had a hacking cough and profuse rusty expectoration, though no definite signs of pneumonia could be made out. The output of urine increased from ten ounces on the first day to thirty-two on the third day and with forced fluids from that time for fully six weeks the total output for twenty-four hours was not below ninety-six ounces daily. After the first ten days there were no casts and no pus in the urine. After the first twenty-four hours no dressings were applied to the burned areas, the bedding being elevated on racks with electric bulbs hung on them. As fast as necrotic tissue loosened it was removed, but the discharge from the granulating surfaces was profuse. Both groups of flexor tendons sloughed off at their muscle origin and were amputated. Similarly the flexor longus pollicis tendon sloughed and was cut at the same level. On July 19 three large Thiersh grafts were transferred from the right thigh to the right forearm, and all were successful. At another time five grafts were made and all were successful and later seventeen small grafts were applied after the Staig-Davis method; all of these were successful but one. The patient finally left the hospital on October 17, but required three dressings weekly until December 18, at which time he was allowed to go home for the holidays with everything healed but the bridge of scar tissue across the posterior axillary fold. When the patient left the hospital there was no motion below the elbow, and motion at the elbow was limited to about 40 degrees. Abduction at the shoulder was limited to about 40 degrees by the contracture in the posterior axillary fold. At the present time the posterior axillary fold was but one inch lower than on the opposite side and abduction could be carried to 120 degrees. There was flexion at the elbow and extension was less than 20 degrees limit- the patient would have a hand which was fairly useful, ed Pronation and supination were to full range. The though the anesthesia in the palm of the hand and the palmar surface of the fingers would probably make it median nerve sloughed out with the flexor tendons, but the ulnar nerve was functionating. The prospect was that dangerous to undertake any rough work.

X-Ray Keratoses on Hand of Radiologist Cured by Radium.—Dr. SINCLAIR TOUSEY reported this case. He stated that his own hands had long been disfigured by growths which had resulted from his *x*-ray work. The lesions were of two types. A very few were raised, almost pedunculated, healthy looking fleshy tumors with a black pigmented apex. About thirty others were exceedingly hard black lumps projecting slightly above the surface of the skin. The smaller ones had a tendency to undergo spontaneous exfoliation about once a year, leaving a healed surface somewhat depressed but surrounded by an indurated base. In a very few days a deposit of pigmented granules would take place looking under the microscope, like particles of anthracite coal, and in a week or two the black lump would have been renewed. The smaller lumps of this kind could be curetted out at any time, leaving a dry reddish granular depression upon which a similar growth would be quickly reproduced. There were some larger ones which never came away spontaneously. Some of these were associated with deep painful fissures of the skin. For years the author kept these unsightly excrescences under some kind of control by the application of salicylic and lactic acids which removed them temporarily. Another application which was not permanently successful was full strength formalin. About a year ago at the suggestion of a general surgeon, two of the larger growths were treated with pyrogallic acid, one dram collodion, one ounce, applied three times a day. This application was not painful at first but later produced terribly sore fingers with suppuration beneath the areas destroyed. Eventually the growth came away and the ulcer healed, but the growth returned in a short time and all the suffering had been in vain. Dr. Caldwell had succeeded in curing certain *x*-ray lesions of his hands with radium and the author determined to try it on his own hands. He selected one of the largest growths which resembled a horn on the dorsum of the interphalangeal articulation of the left ring finger. The field of application was limited by a protective sheet metal rendered adhesive by coating it with double faced adhesive plaster. Twenty milligrams of radium element enclosed in a small glass tube covered with the thinnest soft rubber was kept almost in contact with the skin for thirty minutes. The growth had previously been pared down almost to the bleeding point with a scalpel. The result of the application was not perceptible for about ten days, and then the skin became somewhat red and shiny. Twenty days further passed without any decided change. During this month the pared off keratosis had not sprung up again, as would have been the case had the radium not been applied. On the thirty-first day the reddened skin around its edges was discovered to be loosened from the underlying tissues and in a few minutes the entire destroyed growth was frisked off like a scab. The surface beneath was pink and tender but fully healed and now, ten weeks after the application of the radium, the skin was strong and presented no marks of any kind. He had been treating the other growths seriatim and all came away in about a month, leaving a healthy surface beneath. Dr. Tousey presented the histological report from Dr. Sondern who concluded with the statement that evidently *x*-ray keratoses while in the precancerous state were curable by radium applications. The double coated adhesive plaster referred to was in regular use for different mechanical purposes. It consisted of cloth coated on the back with rubber adhesive plaster mass and on the other side with zinc oxide plaster mass. For radium therapy the back of the plaster was applied to a silver half dollar or some other piece of metal serving as a handle or as a means of shielding the patient's fingers from the radiation and the face of the plaster was fastened to the tube of radium with whatever covering was desirable to filter the radiation or prevent direct contact with the patient and contamination.

A Case Illustrating the Value of Bile Feeding in Patients with Biliary Fistulæ and Obstruction of the Common Duct.—Dr. JOHN C. A. GERSTER presented a man of 44 who was admitted to the Third Surgical Division of Mt. Sinai Hospital intensely septic with jaundice, high fever, and a large mass in the right hypochondrium. A large pericholecystitic abscess was evacuated; the gall-bladder was opened and drained; a severe grade of cholangitis was present. Convalescence was very slow. Finally at the end of seven weeks the patient presented the following picture: While he was free from fever and was able to be up and about, nevertheless his general condition was very poor; his pulse was weak; there was marked emaciation; all the bile escaped from the fistula; the stools were white. Temporary closure of the fistula gave rise to cramps and jaundice. There evidently was obstruction of the common duct. The patient's great weakness forbade operation. To effect an improvement in his condition, all the bile escaping from the fistula was collected and was introduced into the stomach by means of a stomach tube twice a day (8 ounces each time). There was no nausea at any time. The appetite became much better. A remarkable improvement in general condition took place. At the end of two weeks it was deemed

safe to operate. Under local anesthesia and nitrous oxide-oxygen anesthesia, a stone impacted in the papilla of Vater was removed. Convalescence was complicated by acute cardiac decompensation on the second day after operation which responded to appropriate medication; after that his case ran an uneventful course. Dr. Gerster concluded by saying that the administration of bile in physiological quantities, as just described, was a method for materially improving the condition of debilitated patients with biliary fistula and common duct obstruction which seemed worth extended trial.

A Report on Operating Room Technique in Roosevelt Hospital.—Dr. GEORGE E. BREWER presented this report. He stated that it was evident that every infection occurring in a clean wound, and every infected wound that was not rendered sterile by the primary operation where this was possible, resulted in increased suffering and delay in convalescence to the patient and an increased expenditure of money, time and effort on the part of the Hospital and Attending Staff; that while accidental infections would occasionally occur even in the best regulated institutions, and while it was frequently impossible to render a given septic wound sterile by the most approved and skillful operative treatment, a conscientious surgeon by perfect technique and an ever vigilant watchfulness would reduce these unfortunate accidents to the minimum. His interest in operative technique with a view to avoiding wound infection dated back to his first year of service as attending surgeon to the City Hospital, 1895, when he had found that 39 per cent. of all clean operative wounds occurring in his service became infected. Various reforms in technique resulted during the following four years in a reduction of infection in clean cases to 3.2 per cent. During the course of his studies which effected this change he visited the more important hospitals in this city and in Boston, Baltimore, and Philadelphia. When he asked the question "How much infection do you expect in clean cases?" the answer was almost invariably "Practically none." Later conversations with members of the house staffs and observations during ward visits led him to the belief that the "practically none" though it represented the honest opinion of the visiting surgeon, was not based on accurate records. He believed his own off-hand estimate of the percentage of infections would fall far below the actual figures. He was strongly of the opinion that the only way to obtain the best technical results was to keep an accurate record of infection in every case submitted to operation. Dr. Brewer said he had made reference to the City Hospital because he wished to call attention to the fact that in an institution where the patients, as a rule, were seriously handicapped by a low vitality due to malnutrition, dissipation and disease, a somewhat exaggerated technique was necessary to obtain results comparable with those in other hospitals. Another factor was that of air infection, which was greater than in other institutions. To overcome this source of infection they found it necessary to cover all instrument trays, wash basins, irrigators, and pitchers with tents or covers of sterile muslin and to employ irrigation of the wound during their operative procedures. He had found when he was appointed to Roosevelt Hospital that many of the unusual technical methods used in the City Hospital to meet the unusual conditions of that institution were unnecessary and that even better results could be obtained by somewhat simpler but equally effective technique such as was employed by Dr. Charles McBurney and Dr. Robert F. Weir. While this was in part due to the more perfect operating room equipment and to a more thoroughly trained staff of assistants and nurses, the most important factor seemed to be the better physical condition of the patients. Dr. Brewer related the details of several outbreaks of infection in Roosevelt Hospital, the sources of which were discovered by careful bacteriological tests of all material coming within range of the operation. Repeated bacteriological tests since that time had demonstrated that their materials were not only free from living bacteria but also spore free. For some years, both before and after this investigation, their results seemed so satisfactory and the accidental infections so far apart, that no special inquiry was made to ascertain the exact number or percentage. During the early part of 1911, however, one or two unexplained infections occurred which led the writer to inaugurate on the first surgical division, a weekly report of every case operated on, the condition of the wound area before operation, and the condition whether clean or infected at the first and subsequent dressings. Any case of unexplained infection was referred to a committee for investigation. They now had a complete list of these reports since January 1, 1912. During this period their technique might be summarized as follows: Whenever possible a tub bath was given to the patient the night before operation, followed by shaving the wound area, and the application of a soap poultice. After from four to eight hours this was removed, the part scrubbed with soap and hot water for five minutes, and a wet bichloride dressing applied. On the operating table this dressing was removed by a sterile assistant, the parts rescrubbed for one minute, douched with ether, alcohol, and 1-5000 solution of sublimate. The wound area was surrounded by sterile towels and the entire body covered by sterile sheets. Sterile caps, gowns and gloves were worn by all participating in the operation. The towels around the wound area were flanged as often as soiled, and always before the insertion of the cutaneous sutures. Their method of sterilizing their materials did not differ in any material way from that employed in any modern surgical clinic. Frequent bacteriological examinations demonstrated that their materials were sterile. They did not wear face masks because they had a system of signals by which they were enabled to avoid talking during operations. The tables submitted gave their results in the clean cases, and would show the number of infected cases rendered sterile by their operative treatment. It would be seen that for the first six months in 1912, the percentage of infection occurring in clean operative wounds was 2.4 per cent. This was larger than they had anticipated and certain additional precautions were instituted. For the second six months of 1912 the percentage of infection was 1.2 per cent. For the first six months of 1913 the percentage was 1.8 per cent. and for the last half of 1913 1.6 per cent. if they included three cases in which infection occurred as a result of using an unsterile solution of novocaine for local anesthesia, for which none of the operative room staff was in any way responsible. For the six months ending July 1, 1914, no infections occurred in the 273 clean cases. From July 1, 1913 to July 1, 1914, only one infection occurred in 516 cases for which the operating staff could be held responsible, a little less than 0.2 per cent.

Dr. FENTON B. TURCK said that the condition of the patient that favored autoinfection was quite as important as the care in the prevention of infection from extrinsic sources. In 1896, 1900 and 1903, he carried out a series of experiments on animals, which were published at the time, and compared them with studies in cases operated on by Drs. Senn, Murphy and others. It was found that shock or marked splanchnic congestion precipitated by trauma, anesthesia, etc., lowered the resistance so that even saprophytes such as staphylococcus albus from the skin and colon bacillus caused post-operative infection equally as fatal as the more virulent groups from extrinsic sources. Normal animals used as controls gave negative results. The essential things, which he had previously presented, and treatment outlined, were the prevention of shock and prompt reduction of splanchnic congestion and increase of the resistance—the antibodies—on the part of the patient.

New Points in the Handling of Recent Fractures of the Femoral Neck.—Dr. R. H. M. DAWBARN presented this communication, which he prefaced by referring to the use of mnemonic keys as a help to memory, and suggested "Pine Branches" as naturally associated with the brittleness of old bones. The chief signs of fracture of the femoral neck were as follows: Pain and tenderness, inability (disability), neck shortening (noticed upon rotation), external rotation of limb. The signs associated with shortening were: Bryant's triangle, Roentgen rays, Allis's sign, Nelaton's line, Chiene's lines, Hennequin's test, ecchymosis, sound. It would be noticed that there were just twelve of them, and the thirteenth (always unlucky) was crepitus. This emphasized the danger of using this sign as an intentional attempt at diagnosis, which often did harm rather than good by breaking up a kindly impaction. As to the inability, preventing the patient from lifting the foot from the bed, which had been considered pathognomonic of femoral fracture, recent experience, confirmed by the *x*-ray, showed that they must add acetabular fracture to that of the femur as causing this curious sign. Regarding rotation of the limb outward, Dr. Dawbarn said that just once he had seen the opposite condition, and then it was carried to a degree of inversion which was deceptive. Whenever

this break occurred and the foot remained with the toes forward, or but little rotated outward, one was fairly certain to be right in assuming impaction to be present and the prognosis exceptionally good from simple immobilization, preferably of Whitman's method. The various aids to diagnosis named after their famous inventors should be verified whenever possible by the roentgenograph. The writer protested against the custom of measuring for shortening from the anterio-superior iliac spine to one of the malleoli. It was always easy to feel the upper edge of the tibia just at the inner side of the patella, and this should be the lower limit as it was the limit of the bone one was measuring. As a method of measuring the degree of shortening, Dr. Dawbarn suggested that the patient be laid flat on his back on the floor, with a pillow and blanket, his legs semi-flexed, keeping the knees together. Thus his legs would be horizontal and his thighs vertical. Now the difference in height of the two patellæ, as indicated by a ruler or book laid flat upon the uppermost one, showed at a glance the degree of shortening, if any. Sound as a means of diagnosis had been badly neglected. He had been teaching it, however, for twenty-odd years under the name of "osteophonic percussion." There was no sign, except the roentgen ray, whose guidance should be placed before this in reliability to the experienced ear in most instances. This method indicated the presence of a layer of muscle, however thin, crushed between the fragments, preventing bony union, whereas if bones were in good apposition there was scarcely any change in the conductivity. In suspected neck fracture the stethoscope was placed over the great trochanter while percussion was firmly and repeately made by an assistant upon the anterio-superior iliac spine, until the listener was quite familiar to the pitch and intensity of the note produced; then this was repeated on the opposite limb and the sounds compared mentally. If it was the shaft and not the neck that was suspected, the stethoscope was placed as before and the assistant percussed strongly upon one or the other femoral condyle. It was curious to what an extent this valuable test was neglected. His excuse for mentioning it was that it was not even mentioned in most of the leading text-books. In considering the treatment of these fractures the speaker said the first question which presented itself was, "When does the exudation of callus, especially in elderly people, begin, and when does it end and calcification begin?" The statements found in the literature were very indefinite. His experience seemed to show that in middle life in the fracture, say, of the tibial shaft, the exudation of fibrin began at about the tenth day, continued freely to about the twentieth day, at which time the deposit of lime salts and great activity of osteoblastic cells began. In elderly people, after fracture of a bone, and notably of the femoral neck, it was fair to assume that these processes began later and continued longer and less actively than in younger people. If they said that callus ceased being deposited after forty days they should perhaps be not wide of the mark. They might even concede a further period of twenty days, but if two months at least had elapsed with the fragments in poor mutual relation, then, in his experience, it was no longer wise to do anything except to operate. He emphasized the point that there was a date after fracture beyond which it was hopeless to expect results save by operation. A short period of Buck's extension was advisable alike for Whitman's method part to overcome shortening. In operating the joint was opened by a straight incision along the outer edge of the tensor vaginæ femoris muscle. The fragments were freshened, loose pieces removed, and a scalpel puncture and for the operative method to tire the muscles and in made four fingers or less below the top of the great trochanter, exposing a spot on the outside of the shaft through which they drilled until they reached the dense bone of the convexity of the head (the limb was held properly in extreme abduction). They then introduced into the drill hole a rather slender trocar and cannula fitted to the nozzle of a small syringe or else used a coarse spinal needle and its regular syringe, although the syringe was detached. This aspirating needle with its obturator in place was passed along the drill hole until its point appeared on the surface of the fracture. Care should be taken to measure the extent to which its base extended outside the shaft of the femur, so that the point would finally be left between the two main fragments when they were nailed together. With the limbs in extreme abduction the fragments were spiked together, using an aluminum nail. Aluminum was chosen because, varying somewhat with the patient and the character of the metal, it was absorbed in about two years' time. He did not see that a bone spike taken from the patient's tibia or that of an appropriate donor possessed any advantages over the aluminum spike. The nail was driven home guided in pat by the cannula already in place and partly by the drill hole alone. The capsule of the joint was sutured and the wound closed, and the same kind of a plaster-of-paris outer splint applied as was used in a nonoperative case. To cause nature to do her work in the exudation of callus he injected freshly boiled glyceride of tannin, 10 per cent. On an average 2 to 4 c.c. were thrown between the bone ends. He had used this method for some years before venturing to report on it, but he now felt convinced that this plan would prove helpful in appropriate cases. At this point, especially in the elderly, they had no guarantee that nature would go on and finish the work by changing the callus into bone. To hasten this process he administered regularly three time daily, after the food, and for a long period, phosphide of zinc, beginning with 1/50 grain doses in pill form and increasing slowly, combined with rather full doses of calcium lactate. While the effect of this medication was rather difficult of proof his experience with it in the City Hospital forced him to believe that it had its value and was worth continuing.

A Controller of the Throat and Palate for General Anesthesia.—Dr. JOSEPH E. LUMBARD presented a new instrument which was specially indicated for obstructed breathing caused by the falling back of the tongue; it was also used for obstructions of the nose and mouth during general anesthesia. It obviated the barbarous methods of tongue retraction and jaw holding. Some such instrument should always form a part of every anesthetist's outfit. The advantages over other similar instruments were easy introduction; would not become obstructed with mucus; quickly cleansed; easy to maintain in position, and could not be compressed by the teeth or the gums.

Books Received.

CARDIOVASCULAR-RENAL DISEASE (ARTERIOSCLEROSIS).*

BY LOUIS FAUGERES BISHOP, A.M., M.D.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

You are all familiar with the characteristics of the man or woman who is suffering from cardiovascular-renal disease, but no one of you yet has been able to suggest a less cumbersome name for the disease that would include the other organs that are involved. Arteriosclerosis is such a name, but it draws too much attention to the condition of the arteries, which in fact are only participating organs in a general condition. To be sure, custom has ordained that these persons should be regarded as suffering from heart disease, kidney disease, or hardening of the arteries, according as one or the other produces the most striking symptoms. The disease itself has no symptoms until such time as some organ is involved.

The old point of view—that in which you and I were trained—regarded the structural changes in the various organs as the disease from which these persons were suffering, and when we had decided that there existed a sclerosis of the kidneys we said that the man was suffering from interstitial nephritis; when we found an enlargement of the heart, we said that he was suffering from hypertrophy of the heart; when we found thickened blood vessels, we said he was suffering from arteriosclerosis. We were not even taught to make a sharp distinction between calcification of the arteries which is physiological with advancing years and the increase in connective tissue in the arteries that is found uniformly as part of this general disease. While it is the physician's duty to know what structural changes have already taken place in the organs of the man who is to be treated, this knowledge suggests no basis whatsoever for hopeful treatment.

My own conception of cardiovascular-renal disease is of a process that is going on in the body which, if unchecked, results in pathological changes in the organs. This process is a disturbance of bodily physiology, and holds out a very great hope of treatment.

I place the disturbance of physiology in the ultimate cells of the whole body, and find it based upon the disturbance of the physiology of the cell whereby it has undergone a change in its relation to those materials by which it must be nourished and furnished with energy for its activities. This can be expressed in the term "a disturbance of metabolism."

To understand this we must consider the whole question of food intake, digestion, and assimilation, and must revise some teaching of our college days.

There are two digestions: On the one hand, the digestion by the stomach and intestines of the food and its preparation for absorption and its passage into the circulation; and, on the other, the digestion by each individual cell of these food products.

A very little observation soon shows us that the common experience of mankind and the traditional belief of the profession point to protein foods as the ones involved in the production of cardiovascular-renal disease.

A surprising fallacy that has been regarded as almost axiomatic for a long time is the supposed conversion of the multiplicity of proteins that are taken into the intestinal tract into the particular protein characteristic of man during the passage of this material through the intestinal wall. Personally, I always balked at the acceptance of the existence of this marvelous function in this delicate membrane, and I never could understand why it was that after a full meal of animal food—eggs, fish, or meat—there was no perceptible change in the blood, though the proteins had disappeared from the intestinal tract.

We all know that proteins are broken down into amino acids in the intestinal tract, but what became of these acids was a good deal of a mystery. It is now known that the intestinal wall has no such function, but that when a meal of animal food passes through the intestinal wall into the circulation these food materials in the form of amino acids are stored in the flesh, particularly in the muscles, and later on more gradually converted into proteins usable for the nutrition of the cells.

So long as the cells are normal in their reaction the presence of these animal proteins is without harm and constitutes a natural, intermediate event between digestion and metabolism, and the cells are able safely to appropriate to their nutrition and activities their necessary food supply. When the relation of the cell to a protein is disturbed and that particular protein is allowed to come in contact with the cell we have an irritation and disturbance of metabolism, which if general and long-continued results in cellular damage and the gradual development of the condition which for the purposes of this paper we have called cardiovascular-renal disease.

To understand the nature of this disturbance of metabolism we must bring to our aid the findings of modern serology, to show how and in what way the cell may lose its proper relationship to proteins. The most striking example of this disturbed physiology is brought to light by the phenomena of anaphylaxis. Anaphylaxis is a violent disturbance

*Address before a joint meeting of the Medical Societies of the Counties of Allegany, Genesee, Livingston, and Wyoming, July 15, 1915, at Glen Iris, Letchworth Park, N. Y.

of the cell on coming in contact with a protein to which it has become sensitive. The cells of a guinea pig can be sensitized to white of egg by injecting white of egg into the circulation, and later on the animal may die a violent death when additional egg white is introduced.

The exact steps by which human beings become sensitive to food proteins is not by any means clear, but the fact remains that they do become so sensitized, and that proteins introduced through the intestinal tract can produce an irritation of the cells, which if continued for a long period of time results in organic damage, elevated blood pressure, deterioration of the heart, and all the things which go with cardiovascular-renal disease.

An examination of the histories of many hundreds of people suffering from arteriosclerosis has shown in a majority of cases a record of a sensitizing event. This may have been a severe illness from an infectious disease, particularly typhoid fever, chronic appendicitis, a period of great nervous strain, or some acute food poisoning. It seems to be a fact that up to the point in the history of these individuals where proteins were badly borne the latter had been harmless, while from the time that they became harmful they were very harmful indeed, and resulted in cellular destruction, with the replacement of the destroyed cells by connective tissue, resulting in the deterioration of organs.

Founded on these hypotheses I have become a profound believer in the value of dietetics in the management of this condition, and an earnest advocate of those general hygienic measures, hydrotherapeutics, rest, and exercise, which influence the process of metabolism.

The fact that so much of this chemical process takes place in the muscles shows that it is important that the muscular system, particularly the heart, should be kept in order by exercise, and if disordered restored by the same agency under proper supervision.

Arteriosclerosis is a disease without symptoms during the first five years of its existence, and often without objective signs. Pain in the region of the heart is one of the earliest of all symptoms, and is to be explained by the fact that the heart is one of the largest and most active muscles in the body that has a highly organized protective mechanism by which any impairment of function is reflected to the spinal cord and gives rise to pain referred to the distribution of the sensory nerves going through that level. Of course, the muscle itself has no possibility of showing pain.

Again, a disturbance of metabolism often calls for an elevation of blood pressure, so that the heart muscle impaired in its nutrition and an elevated blood pressure constitute the elements causing cardiac pain. This pain is noticed on exertion, but it may be noticed a few hours after a meal at the time when the food proteins are being stored in the heart muscle. A very unfortunate habit of the profession often refers these pains to disorders of stomach digestion, and leads to the neglect of a proper dietetic and physical hygiene until organic change in the kidneys and blood vessels is so far advanced that cure is difficult.

Particularly unfortunate is the fact that the close relationship between the innervation of the stomach and the heart leads in most of these persons to a gastric neurosis accompanied by the production of large quantities of gas. So thoughtless people from time immemorial have blamed serious heart disorder upon a supposed fermentation in the stomach, while in fact the stomach neurosis was secondary to a real disturbance of metabolism involving the heart muscle. Hence, nine times out of ten the early stages of cardiovascular-renal disease are treated as disturbances of gastric digestion.

Just why this supposed gastric pain in the region of the heart is increased by exercise, if it is a gastric pain, I have never heard anyone attempt to explain. I have yet to see an example of pain on exertion at the time of the absorption into the muscles of the proteins of digestion that did not represent a commencing cardiosclerosis, that if untreated did not reveal itself a few years later in arteriosclerosis.

So much for the consideration of the true nature of so-called cardiovascular-renal disease—arteriosclerosis.

Founded upon these conclusions our treatment must be directed to the underlying cause, namely, the disturbance of metabolism. As this disturbance consists in a majority of instances in a loss of tolerance of the cells to particular proteins, and as it does not make much difference in the field of nutrition what protein is used, it is a simple matter in theory to supply the necessary nitrogenous food by a single safe protein. Experience has shown that this safe protein is found in milk, which is the only protein provided by nature exclusively for food purposes.

My experience leads me to believe that practically all well-advanced cardiovascular-renal sufferers are sensitive to meat proteins; that nearly all are sensitive to fish proteins, and that a large part are sensitive to egg proteins. The single exception seems to be with the flesh of fowl, which is tolerated by many who cannot tolerate meat or fish.

In the presence of severe disease all eggs, fish, meat, and stock soups should be excluded. This leaves a much wider dietary than would at first be supposed.

After disposing of the supposed gastric origin and the uric-acid origin of the disease, we have open to us practically all the fruits, vegetables, cereals, fats and oils, with every kind of milk product. We exclude only things which the individual finds from actual and repeated experience to disagree with his stomach.

Alcohol is not specifically harmful, though its side effects are unfriendly to any systematic hygienic treatment.

Tobacco is a matter of individuality. A few people are profoundly sensitive as to their cardiovascular system to tobacco. Most people can use it in moderation.

The second indication of treatment founded on the belief that all these examples of degenerative circulatory disease are in their ultimate analysis examples of chronic food poisoning is attention to the intestinal tract, particularly as to the elimination of stagnating materials. For this purpose the good and tried remedy, castor oil, is so much better than any other that I use it almost exclusively, and as nearly as possible in its pure form.

In starting treatment of a person with cardiac pain, high blood pressure, and albuminuria, I give a full ounce of castor oil every other day for three days, then at the end of a week, then in two weeks, then in three weeks, and follow this by a monthly dose as the rule for a long period of time.

The third element in treatment of the disturbance of metabolism that is the underlying cause of cardio-

vascular-renal disease is found in exercise. Exercise constitutes the best cardiac stimulant, the best pulmonary excitant, and the best remedy for intestinal inactivity. I am accustomed to tell people with high blood pressure that bodily fatigue judiciously obtained out of doors is the best antidote for that condition.

To sum up this conception of the nature and treatment of cardiovascular-renal disease it may be said that we must seek the underlying cause of the disease in the ultimate cell. We must regard the organic changes as the result of the process—not as the disease itself.

In treatment we must primarily treat the disturbed metabolism by cutting off the source of irritation in proteins to which the individual is sensitive, by a diet to which I have given the name "the few-protein diet," because it implies the complete elimination of irritating proteins rather than the diminution of their quantity, the recognition of exercise as the best cellular and organic stimulant, and the use of castor oil as the best single remedy.

In addition to these things we will bring to bear on the treatment of the individual organs such methods as are needed and as our judgment dictates.

Time does not permit of the discussion of the place of iodide of potassium, nitroglycerin, digitalis, hydrotherapy, and many other implements of the art of medicine that are appropriate.

The great enemy of the cardiovascular-renal patient is the supposed specific, whether it be electricity, radium, some fantastic combination of salts, or the latest fashionable combination of iodine. The road to restored health is rugged and beset with discouragements, but the comfortable by-way offered by the supposed specific has led to the subtraction of many years of life from persons who have been so unfortunate as to rely on them to the neglect of the essentials of treatment.

The cure resort as exemplified by the cures of Europe and now by our own Saratoga, makes the strict regimen much pleasanter to carry out, though many cures are constantly being successfully conducted by people in their own homes. The sufferer from cardiovascular-renal disease is often the most valuable citizen in his community and much more worth saving than those liable to succumb to infectious diseases, and if after hearing this paper you can return to your homes with renewed hope that you can help these people I will be more than satisfied with my day's work.

THE SIMPLIFIED TREATMENT OF ANORECTAL AFFECTIONS—RECTAL CONSTIPATION—RESUME OF INTESTINAL STASIS.*

By SAMUEL GOODWIN GANT, M.D., LL.D.,

NEW YORK,

PROFESSOR OF DISEASES OF THE COLON, RECTUM, AND ANUS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE SIMPLIFIED TREATMENT OF ANORECTAL AFFECTIONS.

Examination.—Some physicians base their diagnosis, usually "piles," on finding blood upon the shirt or on the patient's statement that he has pain in the rectum. There is no excuse for not diagnosing anorectal affections to-day because they can be inspected through the proctoscope, the character of the feces can be detected by chemical, microscopic, and macroscopic examination, and the extent and connection of rectal diseases with neighboring organs can be determined by digital exploration, bimanual palpation, fluoroscopic examinations, and radiograms.

Preparation of Patient.—The common practice of surgeons purging patients and deluging the colon before rectal operations courts annoyance and infection, since the field of operation will be bathed with fluid feces, which delays the work, contaminates the wound, soils the dressings, and makes the patient uncomfortable afterward.

For *fistula, hemorrhoidal, fissures, polypoidal,* and other *minor operations* but a few moments are required to prepare the patient, which is done by having him inject a glassful of soapsuds into the rectum to bring away solid feces, after which the mucosa is mopped over with peroxide of hydrogen or other antiseptic, procedures which forestall many annoyances. When the bowel is to be amputated or resected for rectal procidentia, stricture, tuberculosis, or cancer three or four days' preparation is required and the gastrointestinal tract is first cleansed by catharsis and colonic ichthyol 1 per cent. irrigations, and then tied up with an opiate or astringent which insures a dry field of operation.

The parts are never shaved, except where *sutures* are used, and primary union is anticipated because the hair stubs cause great annoyance.

Anesthesia.—Local anesthesia is dependable and indicated in about 80 per cent. of rectal operations, but is contraindicated where one does not know what is required beforehand. Many drugs have been employed, but none are superior to a ½ per cent. eucaine solution, which anesthetizes the part quickly without inducing toxic manifestations.

The writer has successfully operated upon thousands of patients under eucaine or sterile water anesthesia, and has found that preliminary pain is slightly less after eucaine than water and that postoperative pain and bleeding follow eucaine very much more frequently than water anesthesia.

Quinine and urea solutions take longer, but produce anesthesia which lasts hours following operation and prevent postoperative pain, but this advantage is offset by occasional sloughing and retarded wound healing which usually follows their employment.

The writer does not employ adrenalin in local anesthetics, for it primarily causes contraction and later relaxation of the tissues, and he prefers an immediate hemorrhage if bleeding is to occur, so that he can arrest it at once.

Postoperative treatment.—General surgeons are divided in their method of controlling the stools after rectal operations. Many purge the patient, liquefy the feces, and keep him busy and miserable through his frequent visits to the toilet, while others administer an opiate and tie up the bowel for days, procedures to be condemned because the *former* insures continuous irrigation and favors infection through soiling the field with fluid feces and the *latter* leads to excruciating pain and tearing open of the wound when accumulated, dry, and nodular fecal masses are evacuated.

The writer keeps his patients on a regular diet and does not order a laxative unless the stools are hard, when he prescribes mineral oil, fruit, or other

*Read before the Lehigh Valley Medical Association at Delaware Water Gap, Pa., July 15, 1915.

laxative in small doses to soften but not liquefy them, for at one sitting semisolid feces are evacuated without pain or injury.

The former practice of *cauterizing* wounds no longer obtains, and they are *drained* and not *packed*, pernicious procedures responsible for many unhealed sores and fecal incontinence. For cleansing wounds, the swab and cotton moistened in an antiseptic is substituted for copious irrigation, which leaves the rectum filled with the solution, which dribbles out, soils the dressings, and keeps the patient uncomfortable. When healing is tardy the wound is satisfactorily stimulated by placing a gauze pledget moistened in a silver nitrate 6 per cent., ichthyol 10 per cent. or balsam of Peru 20 per cent. solution in it, but when the tissues are irritable and rebel against stimulants methylene blue 10 per cent. is soothing and effective.

Pain from topical applications can be minimized by eucaine or cocaine 10 per cent. applications, but all suffering can be prevented by injecting eucaine ($\frac{1}{8}$ per cent.) beneath the lesion before it is treated.

Pruritus Ani.—Ball's operation for pruritus ani, having for its object the severing of nerves from the skin, is an elaborate procedure and leaves extensive wounds to heal when infection occurs. The writer has modified this procedure so that it can be performed under local anesthesia in ten minutes and the patient need not remain in bed more than two or three days.

External Thrombotic Hemorrhoids are anesthetized by injecting enough eucaine into the pile to turn it white, when it is transfixed with a sharp-pointed curved bistoury, slit open, the clot turned out, and the wound drained to prevent reformation of the tumor. Subsequent dressings consist in cleansing the wound and inserting gauze drains until healing is complete.

External Cutaneous Hemorrhoids are quickly removed with knife or scissors after having been injected with eucaine, which induces complete anesthesia within 20 seconds. Following excision the wounds are closed with catgut or permitted to heal by granulation which is preferable, since there is less danger from infection and postoperative pain is slight.

Many operations have been suggested for the cure of *internal* hemorrhoids, but the following procedures named in the order of their usefulness, viz.: ligature, clamp, and cautery and modified excision operations are the most dependable and less often followed by annoying and dangerous sequelæ.

Ligature Operation.—The ligature operation is generally used, reliable, is rarely followed by hemorrhage or complications, and its technique is simple and can be carried out under local or general anesthesia. Except when there is a special reason for administering gas or ether the writer always operates under sterile water or eucaine ($\frac{1}{8}$ per cent.) anesthesia. Hemorrhoids are brought into view by a small enema, suction pump, having the patient strain, everting the anus, tilting the fenestrated speculum as withdrawn, or by inserting cotton tampons and withdrawing them simultaneously which extrudes the piles.

The hemorrhoid is then injected with water or eucaine until white (which indicates complete anesthesia) incised at the mucocutaneous juncture, ligatured, and removed with knife or scissors.

Remaining tumors are similarly treated and the operation completed by pushing hemorrhoidal stumps above the sphincter. A thick wedge-shaped gauze pressure-pad is then placed over the anus and held in place by a strong T-binder to arrest and prevent bleeding.

Hemorrhoids located high after having been injected through an opening in the speculum are brought downward into the field of operation with forceps.

Formerly following ligature operations patients suffered considerably, and it often became necessary to catheterize them, but since the writer discarded large, heavy, harsh plaited silk for linen ligatures, severe postoperative pain and inability to void the urine have been rare complications because the sphincter and levator ani muscles are irritated less.

Clamp-and-Cautery Operation.—The steps in this procedure are as in the ligature operation up to and including the cut at the mucocutaneous juncture. The pile is then drawn downward, clamped, excised, and the stump thoroughly cauterized. A cauterized hemorrhoidal wound should never be sponged or handled because when the burned surface is broken dangerous bleeding follows.

Rectal tubes and gauze plugs should not be employed in hemorrhoidal operations because they are unnecessary, make the patient uncomfortable, and their removal is attended with excruciating pain or bleeding.

The clamp-and-cautery operation is radical, causes but little suffering, and can be painlessly performed under local anesthesia, but is not as satisfactory as the *ligature* operation, because the patient fears the glowing cautery point and may move, and the cautery frequently fails to work.

Excision.—There are several ways of excising piles, but the most elaborate technique is Whitehead's, which consists in removing the lower two inches of the rectal mucosa or supposed pile-bearing region and uniting the divided mucous membrane to the anal skin. This procedure appeals to the surgeon, but is rarely performed by proctologists and then only in a modified form, because it is difficult, bloody, and frequently followed by infection, hemorrhage, delayed healing, pain, stricture, fecal incontinence, incurable ulceration, loss of sensation at the anal outlet, intolerable itching, or other complication when infection occurs. The writer does not believe Whitehead's operation is justifiable in the treatment of uncomplicated hemorrhoids and has treated more than 200 men and women permanently invalided by Whitehead's operation.

A simple method of excising hemorrhoids is to seize each tumor, cut it off, ligate bleeding vessels, and close the wound with a catgut suture or permit the wound to heal by granulation. Again tumors may be removed in successive steps by alternately cutting and suturing until they have been excised and the wound closed. The advantage of these operations over Whitehead's is that a stricture will not follow because healthy strips of mucosa are left between the denuded surfaces and the bowel cannot retract.

Injection Method.—Since popularization of operative procedures under local anesthesia, the injection treatment of hemorrhoids has become almost obsolete, but quacks continue to use the method since they are unfamiliar with the newer technique.

The injection of protruding and bleeding internal hemorrhoids with a 30 per cent. solution of carbolic acid sometimes works magic and stops bleeding and protrusion immediately without detaining the patient from business or causing much pain; but in

other cases under similar conditions, the treatment is followed by considerable swelling, great pain, sphincteralgia, sloughing, abscess, and fistula, phlebitis, pyemia, a tedious postoperative treatment or imperfect cure, and a number of deaths and annoying sequelæ have resulted from the procedure. In recent years the author has had no occasion for injecting piles because under eucaine anesthesia he has been able to painlessly remove hemorrhoids within five minutes without a lengthy convalescence, leaving dangerous or distressing sequelæ and with the assurance that a permanent cure will follow.

Fissure.—When non-operative measures, viz, keeping the feces soft, cleansing the wound, and topical applications of silver, ichthyol, or balsam of Peru (8 per cent.) have failed to heal a fissure, an operation is indicated.

Three surgical procedures—*incision*, *divulsion*, and *excision*—have been recommended in the radical treatment of *fissure-in-ano* or painful ulcer.

Fissures do not heal because the wound obtains little rest, owing to sphincteric contractions, consequently it is necessary to select an operation which will place the anal muscle at rest.

The *incision* (division) operation is the simplest and most reliable procedure, causes the least suffering, and gives the quickest and best results. Formerly the writer favored divulsion, but now he incises the *anal canal* because this puts the external and internal sphincter muscles at rest, allows the wound to heal promptly, and widens the rectal outlet, which lessens the possibility of a future tear and often cures constipation. In his earlier operations he introduced a curved sharp-pointed bistoury into the rectum and divided the sphincter by withdrawing it. The operation arrested sphincteralgia, but the wound required from three to seven weeks to heal and he decided that delayed healing was due to imperfect drainage of the cup-shaped cut. This defect, in the technique was overcome by substituting a straight probe for the sharp curve-pointed bistoury. The following procedure has been successfully employed by the writer in hundreds of cases without a complication.

Using his goose-necked anesthesia syringe, a few drops of eucaine is injected into and beneath the skin posterior to the fissure. The needle is then pushed forward—upward—and the sphincter and lower rectum are anesthetized. Using his scissors having sharp- and probe-pointed blades he passes the sharper through the tissues upward and posterior to the lower rectal wall for an inch or more at the same time the probe-pointed blade passes up the bowel. With one cut the skin and sphincters are divided, leaving a clean wound, which is drained by a gauze pledget. Afterward the wound is treated as following fistula operations. Good results are also obtainable by dividing the muscle in the posterior median line on either side or by a posterior V-shaped incision. Some surgeons advise *partial* division of the sphincter, but this procedure is unsatisfactory because of the difficulty in knowing how deep to cut and it does not put the muscle completely at rest, which is essential for a cure.

Divulsion is popular, but the writer discontinued it because the paralysis induced by stretching of the sphincter does not always last long enough to permit the fissure to heal. Stretching of the sphincter may be done gradually with bougies, or quickly with the fingers under local or general anesthesia. The writer has treated cases where fecal incontinence followed careless forcible divulsion of the sphincter with mechanical dilators or the fingers and has seen multiple large rents caused by the stretching.

Excision.—Fissures should not be excised because considerable time is required, infection frequently follows, and the results are unsatisfactory. This procedure consists in trimming the edges of the rent and closing the wound by sutures or permitting it to heal by granulation and the operation is not effective except when accompanied by division or divulsion of the anal muscle.

Ulcers located near the anus require the same treatment as fissures since they seldom heal until the sphincter muscle has been divided. Lesions higher up are usually numerous, large, deep, and caused by syphilitic, tuberculous, dysenteric, entamebic, bacillary, or catarrhal colitis. In this class of cases the bowel should be frequently irrigated with antiseptic, stimulating, or soothing solutions (silver nitrate, ichthyol, or balsam of Peru 1 per cent.) with the patient in the knee-chest or inverted posture, and lesions low down should be individualy cauterized or treated through the proctoscope or sigmoidoscope by topical applications. When these measures fail, provision should be made for through-and-through bowel irrigation by *appendicostomy*, *cecostomy*, or the writer's *entero-cecostomy*, which provides a means of irrigating both the ileum and colon separately or at the same time.

Fistula.—There are many types of fistulæ, but the writer will not describe the operative measures of each because the underlying principle is the same in all. The more common or complete type of fistula may be operated upon by either the *division* or *excision* method.

Division is the best procedure because the technique is simple, requires but about five minutes, the results are satisfactory, and fecal incontinence seldom follows. When the sinus is divided under local anesthesia the tissues immediately above it are injected with eucaine until *blanched*, care being taken to prevent the needle from entering the tract. The end of the groove director is passed through the outer and then the internal opening into the bowel where it is caught by the finger, brought outside and left resting across the anus. All overlying tissues are then severed with a sharp-pointed bistoury, or the director may be dispensed with and the tract divided with the aid of the writer's probe-pointed fistula scissors.

Excision Operation.—Here a probe is introduced through the sinus and brought out through the anus, where the two ends are twisted together, so that the probe can be used as a guide and tractor. The sinus is then quickly dissected out by a succession of cuts made on either side and behind it. When the tract has been removed, the divided ends of the sphincter and wound edges are accurately approximated with deep and superficial chromicized gut sutures and covered by a dry dressing.

Blind Internal Fistulæ running downward under the sphincter and skin are difficult to operate upon. Formerly, time was lost and false passages were made in attempts to locate the sinus by cutting down upon it, but with the writer's grooved director the operation has been simplified, viz., His angular grooved director is introduced into the rectum until its probed point can enter the opening and be drawn downward through the sinus until the integument bulges. It is then brought out

through an opening made for the purpose and allowed to rest across the anus while the overlying structures are divided.

If the angular director is not at hand, the indurated tract is located and cut down upon, after which an ordinary director is introduced from without and the sinus divided in the usual way.

There is no danger of fecal incontinence following fistula operations where the *sphincter is cut at a right angle, the wound is drained and not packed* and *the skin and mucous membrane are prevented from growing down into the cut and separating the muscle ends.* The dressings are changed when soiled and are gently replaced to prevent destroying fresh granulations, which delay healing and favor incontinence.

Stricture.—Formerly rectal stenoses were treated by *forcible* or *gradual divulsion*, but this dangerous practice has been abandoned except when the constriction is within three inches of the anus, because many deaths have followed rupturing the bowel above the peritoneal attachment.

The rational treatment of strictures consists in *dividing them under local anesthesia when low down, excising the diseased gut when higher up* and performing *colostomy* in inoperable cases.

Polyps.—Polyps which protrude are anesthetized with sterile water or eucaine, *ligated* and *cut off* or *excised* by the *clamp-and-cautery* operation. When situated high they are located through the proctoscope and *twisted off* (torsion) or *removed by placing a Gant valve clamp upon their pedicles*, which causes them to quickly slough off in a few days without causing pain.

When polyps are numerous and scattered throughout the colon and cause a foul discharge or obstruction, appendicostomy, cecostomy, colostomy, or excision of the diseased colon or rectum is indicated.

ANORECTAL CONSTIPATION.

Surgical constipation or *intestinal stasis* occurs more frequently than is believed. Occasionally it is induced by ptosis, pericolic membranes, chronic invagination, angulation, volvulus, adhesions, Lane's kink, ileocecal valve incompetence, or other abdominal lesion, but *infrequent* and *incomplete* evacuations responsible for intestinal autointoxication are located in the *rectum* three times as often as the abdomen.

Anorectal constipation may be induced by growths, strictures, or inflammatory conditions, but stasis here usually results from:

1. Narrowing of the anal canal.
2. Hypertrophy of the rectal (Houston's) valves.
3. Hypertrophy of the levator ani muscle.
4. Hypertrophy of the sphincter muscle.
5. Coccygeal deviation.
6. Hypertrophy of O'Beirne's sphincter.

1. Narrowing of the anal canal: This ailment, a frequent cause of painful defecation and constipation, can be corrected in five minutes by anesthetizing the posterior median rectal wall upward for two inches and painlessly splitting the canal with a probe-pointed bistoury under eucaine anesthesia.

2. Hypertrophy of the rectal (Houston's) valves.—Martin's cutting operation requires considerable time, is accompanied by hemorrhage, frequently followed by infection, and puts the patient in bed. The writer's valvotomy is not accompanied or followed by complications, can be performed in a moment, and permits the patient to return home. It consists in placing one of his clamps upon the valve which it divides by pressure necrosis in from three to five days, depending upon the amount of fibrous tissue in the submucosa.

3. Hypertrophy of the levator ani muscle.—Constipation from this source is usually characterized by fragmentary stools, frequent micturition, and uneasiness in the prostatic region. It is easily cured by dividing the muscle laterally or in the posterior median line. In either case the cut should be brought out through the anal skin and drained, otherwise infection may ensue.

4. Hypertrophy of the sphincter.—The anal muscle is painlessly divulsed with the fingers or divided under infiltration anesthesia, the latter being preferable because it permanently widens the anal outlet.

5. Deviation of the coccyx.—Where the coccygeal tip bends the rectum inward it induces constipation. The writer's operation for removing the bone is practically bloodless and requires but three minutes, a pair of heavy blunt-pointed scissors, a hook, Hagedorn needle, and catgut.

With the first cut the coccygeal tip is exposed and hooked up. Then the lateral attachments are severed and the bone removed by three successive cuts directed outward, after which the wound is closed by three chromicized stitches.

6. Hypertrophy of O'Beirne's sphincter.—This muscle, located at the narrowest part of the large intestine (rectosigmoidal juncture), is rarely mentioned though it frequently causes intestinal stasis. When the mucosa is irritable, inflamed, or ulcerated, rectocolonic irrigations of ichthyol or balsam of Peru (1 per cent.) are indicated, but better results are obtained when they are alternated with an oil combination containing bismuth poured into the sigmoid flexure through the proctoscope with the patient in the inverted posture.

When obstipation is almost complete or enterospasm is a complication, this treatment should be reinforced by hot fomentations and belladonna with an opiate which induces relaxation of the longitudinal and circular muscle fibers. Where the gut is strictured at O'Beirne's sphincter divulsion is unsafe, and it should be resected or excluded.

If the writer had time, an interesting description could be given of *appendicostomy, cecostomy, ileosigmoidostomy, colectomy, sigmoidopexy,* and other procedures successfully employed in the treatment of *myxorrhea membranacea* and *myxorrhea colica* and the manifold colonic lesions responsible for *chronic diarrhea* and *constipation*, which are often unsatisfactorily treated by dieting and internal medication.

RÉSUMÉ OF INTESTINAL STASIS.

We are indebted to Bouchard and Metchnikoff for emphasizing the frequency with which *constipation* is complicated by *intestinal autointoxication* and Lane for pointing out the frequency and *end-results* of intestinal stasis induced by *chronic bowel blocking* or *obstipation.*

Gastric or intestinal stasis may be *acute* or *chronic*, but the former is not serious because it is quickly corrected. Stasis of the alimentary tract is usually encountered in the intestine (the colon and first part of the ileum) and has generally been present a long time before it is discovered or cured.

Definition.—Chronic intestinal stasis is characterized by atony or bowel blocking wherein chyme and feces are intermittently or regularly delayed in

their downward passage, drainage is interfered with and *toxins* accumulate and enter the circulation in quantities greater than the emunctories can eliminate to cause toxemia.

Etiology.—The author believes that intestinal stasis may be induced by *constipation* (*atonic, spastic, or fragmentary*) or *obstipation* (*any mechanical obstruction of the bowel*) where the intestinal content is delayed and copremia ensues accompanied by the usual manifestations of chronic *intestinal autointoxication.* Lane holds that constipation does not cause intestinal stasis, but that bowel kinks, pericolic membranes, cecummobile, etc., do and are accompanied by diarrhea, which does not complicate constipation. On numerous occasions the writer has attended otherwise healthy neurotic and elderly patients suffering from atonic constipation who were annoyed by fluid movements when they failed to secure daily evacuations and feces were permitted to accumulate as large masses or irritating scybalæ. In such instances diarrhea ceased when the offending masses had been evacuated by laxatives and enemata.

Chronic fecal impaction from any cause excites an inflammation of the mucous membrane or leads to the formation of sensitive ulcers, stercoral diarrhea, and intestinal autointoxication. Some patients become *immune* to fecal retention and remain apparently well when the evacuations are from three days to weeks apart, while others suffer profoundly from intestinal autointoxication where the movements are delayed but a short time or the bowel is not completely emptied daily. Occasionally accumulated bacteria and their toxins resulting from costiveness act as stimulants and exhilarate the patient who feels worse following emptying of the bowel.

The upright posture is a predisposing cause of intestinal stasis because it puts a strain upon the gut or its mesentery and leads to the formation of adhesions that kink the bowel. In the majority of instances obstipation and intestinal stasis are caused by congenital defects, ptosis, angulations (kinks), volvulus, invagination, dilatation, diverticula, pericolic membranes, extraintestinal pressure, stricture, growths, hypertrophy of the rectal valves, sphincter ani or levator ani muscles, lesions which impede the fecal current.

Pathology.—The changes which take place in and adjacent to the bowel in chronic constipation, obstipation, and intestinal stasis (autointoxication) vary with the etiology and duration of the obstruction, but distortion of one or more of the intestinal segments is usually present and because of the degenerating effect of the accompanying toxemia structures adjacent to and remote from the intestine often undergo changes.

Symptoms, Complications and End-Results.—The symptoms of intestinal stasis which are those of constipation and obstipation plus autointoxication, are so many and varied that the writer will not attempt more than to enumerate and casually discuss them.

The chief manifestations of constipation or obstipation and intestinal stasis are infrequent stools, anorexia, headache, furred tongue, malaise, mental apathy, indifference to social or business duties, insomnia, bad dreams, foul smelling breath and perspiration, sallow or dirty complexion, dizziness, palpitation, despondency, loss of weight, nausea, neurotic disturbances, subnormal temperature, anemia, cold hands and feet, dyspepsia, flabby muscles, numbness, coryza, rheumatic pains, raised or lowered blood pressure, hyperchlorhydria, disturbances of the thyroid gland, degeneration of the breasts, ptotic organs (from loss of fat), abdominal, pelvic, or sacral discomfort and pain, weakened heart action, diarrhea, reflex disturbances causing gastric indigestion and pain in and distant to the intestine, uteric, tubal, appendiceal, ovarian, and vesicular complications (involvement by adhesions or disease).

Other and more serious *end-results* and *complications* caused by bacteria (infection) and toxic agents arising from *intestinal stasis* are degeneration of the bodily tissues, ulcerated gums, endocarditis, pyorrhea alveolaris, degeneration of the breasts, arthritis (rheumatism-gout), loss of hair, appendicitis, syphilis, cystitis, endometritis, salpingitis, cholecystitis, gallstones, peritonitis, affections of the thyroid gland, duodenal dilatation and ulcers, disease of the liver, and bone, abdominal, or pelvic abscess, pancreatitis, degenerative eye diseases and ptosis of the uterus, viscera, or rectum.

Chronic gastrointestinal autointoxication also predisposes the patient to *tuberculosis, cancer of the stomach, pancreas, intestine, breast, gall-bladder* and *ducts, Still's disease, skin lesions, ulcerative colitis,* and other complications, some of which were discovered by Lane.

It is not difficult to determine that a patient suffers from bowel blocking and intestinal stasis, but frequently it is impossible to diagnose the character of the obstruction before laparotomy though the history has been taken, the abdomen examined, the stools analyzed, the bowel studied by stereofluoroscopic inspection, and radiographs of the stomach and intestine have been made.

Treatment.—The treatment of chronic intestinal stasis may be *non-operative* or *surgical.*

The therapeutics of the *non-operative* treatment consists chiefly in regulating the diet, securing daily movements with the aid of laxatives and olive or mineral oil, having the patient rest in bed during painful attacks, exercise in the fresh air, wearing of a supporting binder, and resort to massage, electricity, vibration, hydrotherapy, and tonics to build up the system.

Surgical Treatment.—Largely through the teachings of Lane, many physicians are resorting to surgery much more frequently than is necessary and performing dangerous operations that leave serious sequelæ without benefiting the patient for *unimportant obstructing lesions* causing stasis that could be relieved by the less serious and more conservative procedures. The author believes less colon snatching and *short circuiting* should be done because the *former* often ends fatally and the *latter* frequently leaves the patient in a worse condition than before operation.

The indications for and technique of enterectomy, colectomy, sigmoidectomy, and proctectomy, intestinal exclusion (short-circuiting), colostomy, appendicostomy, cecostomy, and other operations indicated in the treatment of intestinal stasis have been described elsewhere by the writer and need not be considered here.

In closing his discussion of intestinal stasis, the author would urge surgical intervention as a last resort and not because a radiograph seems to show a mechanical intestinal defect.

In conclusion, the writer would urge his audience to study carefully *constipation, obstipation, and intestinal stasis* and to adopt modern methods of

diagnosing *rectal diseases, simplify office treatment,* and *perfect their technique* so that they can successfully operate upon fissures, hemorrhoids, fistulæ, and other minor diseases of the anorectal region without general anesthesia and other objectionable features. Should they do so, he prophesies that advertising *constipation* and *pile* doctors will soon be eliminated, which would be a blessing to the laity and profession.

471 Park Avenue.

THE DIAGNOSTIC VALUE OF BENCE-JONES ALBUMIN IN THE EARLY STAGES OF A CASE OF MULTIPLE MYELOMA.

By GEORGE H. SENSMITH, M.D.,

Attending Surgeon, Bayonne Hospital,

AND

EMANUEL KLEIN, M.D.,

Bayonne, N. J.

Pathologist, Bayonne Hospital.

Mr. A. D. W., age forty-two; occupation, merchant; married; father of five healthy children.

Family History.—Mother died of pulmonary tuberculosis at the age of thirty-seven; father living at seventy in good health; two brothers living and well.

Previous History.—Had usual diseases of childhood. Since has had an attack of paratyphoid fever in 1910 with complete recovery. Had had financial and business reverses for a period of three years (1910-1913). During the month of December, 1913, had an attack of renal colic incapacitating him for two days.

Habits.—Excellent. No venereal history. Absolutely temperate.

Present History.—Patient had no occasion to consult a physician on account of his health until March 4, 1914, on which date he underwent an examination which was made necessary by the Employers' Liability Act of New York State. At this examination he was informed that his urine showed evidences of Bright's disease, and he was advised to consult his family physician. On physical examination at this time it was found that there was nothing unusual in his general appearance, the patient claiming that his general health had been good. He showed, however, most decided evidences of nervousness due to fright produced by having been told that he had Bright's disease.

Examination of his urine at this time showed the following: Color, milky, suggestive of albumin; sediment, plentiful and white in color; specific gravity, 1.010; reaction, acid; albumin, Bence-Jones; sugar, negative; indican, moderate amount; bile, negative. Microscopic examination, amorphous urates, acid phosphates; casts were not found in this specimen; few pus cells.

Subsequent examinations showed a persistence of the Bence-Jones body. In all twelve to fifteen specimens taken at different times were submitted. Our diagnosis rested among three conditions, viz., (1) multiple myeloma, with which this body is most frequently associated; (2) leukemias, with which blood conditions this body is sometimes found; (3) syphilis, with which this body is infrequently found.

Examination of the patient's blood showed the following: Hemoglobin, 85 per cent.; total erythrocytes per cu. mm., 3,140,000; total leucocytes per cu. mm., 8,000; color index, 1.0. Differential Count.—Polynuclear neutrophiles, 56 per cent.; lymphocites (large and small), 22½ per cent.; mononuclears and transitionals, 18 per cent.; eosinophiles, 3½ per cent.; basophiles, 0. Thus we were able to rule out leukemia.

A negative Wassermann in conjunction with the patient's past history of lack of luetic infection enabled us clearly to rule out syphilis.

Our only conclusion, therefore, could be tha tit was a case of multiple myeloma.

As a rule multiple myelomas are not diagnosed before the clinical picture of multiple fractures particularly of the thoracic skeleton are found. The symptoms in this case, however, were not typical. Subjectively there was present boring pain over the vertebræ, sacrum, ribs, and sternum. Objectively there was tenderness produced by pressure over these painful areas. The literature on multiple myeloma so far as we were able to discover deals almost entirely with advanced cases with the accompanying pathognomonic symptoms of this disease, namely, fractures of various bones, particularly the thoracic skeleton. The case to our minds was therefore, unusual in so much as the only marked characteristic was the presence of the Bence-Jones body in the urine.

Later in the disease the urine showed the same picture both chemically and microscopically with the occasional finding of casts of an apparently waxy consistency. This was by no means a constant finding.

The patient's general physical and nervous condition dating back to the time of his having been informed that he had a serious kidney lesion grew progressively and continuously worse. He continued to fill his position until April 3, 1914, when he had a severe attack of renal colic lasting for a period of twenty-four hours, during which time he was placed under the influence of morphine. He again resumed his occupation, filling his position up to the first of May, 1914, when he found he was no longer able to continue on account of a feeling of extreme exhaustion which had been gradually increasing during the past month. This, together with an ever-increasing nervous fear as to the final outcome of his condition, caused him to take to bed. At this time Dr. Harlow Brooks of New York was called in consultation, who, after examining the pathological reports, without hesitation confirmed our diagnosis, making the statement that he laid but little stress on what he found by physical examination inasmuch as at this early stage the diagnosis could be made in the laboratory only.

From May 17 until the time of his death, May 27, the patient was unable to retain any form, either solid or liquid, in his stomach. Every means to control his vomiting was futile. Rectal feeding was resorted to, but with no avail. The immediate cause of death was exhaustion, coupled with an ever-present and increasing belief that nothing could be done to prevent his death, even though he desired very much to live. This latter fact with the inability to retain food for a period of ten days seemed to hasten his end.

At the necropsy we looked for bone lesions and were not at all surprised to find that the ribs were severed by an ordinary scalpel with a moderate amount of force. The sternum was found so flexible as to be easily doubled upon itself in its long axis, and was almost as easily cut through with a scalpel as the ribs.

Lungs, normal; stomach and intestines, normal; spleen, normal; liver, some hydropic infiltration; heart, normal; kidneys, both were enlarged, pale in spots, capsule stripped easily. Microscopically.—Interstitial changes with round cell infiltration; tubules were dilated and filled with casts, exudate in capsular space with proliferation of Bowman's capsule; hyaline degeneration in glomeruli.

Adrenals showed marked granular degeneration and hydropic infiltration; no fibrosis seemed as yet to have taken place. Pancreas showed hydropic infiltration in islands of Langerhans. Sternum, very flexible; easily cut through with ordinary knife. Microscopically.—showed absorption of bone tissue. In most places bone trabeculæ were absorbed so that medullary canals were coalesced to form one large cavity. This type of cavity was filled with cells nearly all of one type, viz., myelocytic. They contained a large stippled nucleus, frequently eccentric and resembling very much the plasma cell; cytoplasm fairly large in amount staining faintly with eosin; in most places the whole microscopic field consisted of these cells alone arranged in mosaic; here and there a few normal marrow cells could be seen.

Ribs, soft, easily cut through and very flexible. Microscopically.—Showed cartilaginous replacement of an imperfect type; it looked very much like an attempt of nature to replace bone destroyed by the invading myeloma cells.

Most cases of multiple myeloma have an accompanying nephritis showing a small amount of serum albumin as well as the Bence-Jones body; so there is nothing unusual in its presence in this case excepting its severity. The glomerular changes were very marked. What is quite unexplainable is the only occasional findings of casts when the nephritis was so pronounced.

The ordinary tests for albumin are indeed sufficient if given the care such tests deserve. The urine in this case would show a tremendous flocculent precipitate before it even reached the boiling

point, which led to the conclusion by physicians who had previously examined this case, of nephritis. We regret to state also that this error is easily made not alone by general practitioners, but, in this case, by competent laboratory men as well.

Our observation of specimens showed the appearance of this cloud at 50° C., increasing up to 85° or 90° C., disappearing almost entirely at 100° C. On cooling it began to reappear at 70° C., increasing in density and remaining so.

In conclusion we wish to thank Drs. Arthur Mandel, John Mandel, Frank Schaible, and Alexander Frazer of New York, as well as Dr. George McLoughlin of Jersey City, both for corroboration of findings and assistance in the preparation of this case.

EXUDATES IN ARTIFICIAL PNEUMOTHORAX.*

By LE ROY S. PETERS, M.D.,

ALBUQUERQUE, N. M.

PHYSICIAN TO THE ALBUQUERQUE SANATORIUM FOR TUBERCULOSIS.

THE treatment of tuberculosis by the injection of nitrogen or air into the pleural spaces has now been given sufficient trial and the glamour incident to a rather novel, as well as a striking method of treatment having faded, we are able to examine sanely the results and to tabulate into rather accurate form the good and evil incident thereto. I believe there is little doubt in the minds of most tuberculosis workers that we have in artificial pneumothorax a sane procedure, if due thought and consideration are given the selection of cases. In that we are all agreed. On the other hand, that too many have operated without this due thought and consideration and in many cases with disastrous results admits of no argument.

However, it is not within the province of this paper to deal with phases of the question other than from the standpoint of exudates. Herein lies a complication that deserves more than passing notice, for in an experience covering over three years in this method or treatment no one complication has given the trouble and worry, both to physician and patient, as has the occurrence of effusion.

At the end of the first year of our work I was inclined to feel that the question of effusions was somewhat of a myth, and I even flattered myself that our technique was faultless and our knowledge of this form of operative interference was of necessity perfect. Otherwise why should we, as against so many others, fail to elicit fluid in the chests of our patients. Just, however, as I was riding on the crest of this wave of satisfaction our first case developed and, to be brief, many others followed until over 60 per cent. of cases treated a year or more showed varying amounts of fluid. From close observation I now feel confident in predicting that, given the proper amount of time, practically 90 to 100 per cent. of cases operated upon will show varying amounts of fluid. To cite an example, one patient had received gas for nineteen months with perfect results, when suddenly a moderate effusion occurred which went from serous to seropurulent, and finally became purulent, showing on culture and by microscopic examination the presence only of the tubercle bacillus.

*Read before the National Association for the Study and Prevention of Tuberculosis, Seattle, June 15, 1915.

The question as to the cause of exudates is a difficult one. Various opinions have been expressed and there may be reason in all. However, it may be very confidently stated that owing to the uniformity of their occurrence the causative factors must lie within the chest and not without; in other words, the factor of infection in refilling is very improbable. The fact that when a pneumothorax has been established, thus separating the pleural surfaces, an extension of the tuberculous deposits on this surface is easier, inasmuch as there is no opportunity to retard the spread of tubercle by a gluing together of the surfaces as is seen in the average pleura (von Muralt).

Then, too, we have the pleura in an unphysiological position, which, as Kaufmann has demonstrated in dogs, produces an anatomical change in the serosa, as is evidenced by the decreased ability of gas resorption. One has a right to expect that the infected pleura is particularly disposed to exudative inflammation under these changed relations. Forlanini observes that exudates occur after exposure of cold or from exertion, and mentions the fact that the transitional seasons, especially March and April, show the greatest number of such cases. In our experience we are able to bear this out to a certain extent, our greatest number developing in the change from our excellent fall climate to the winter.

In my opinion there is also an irritative effect of the gas pressure on the layers of the pleura, even though minimum pressure is produced. The very fact of a foreign element within the pleural cavity must of necessity cause inflammation with its attendant exudation. I see little, if any difference, in the effect upon the pleura of the different methods of operation, although I believe all Americans, at least, used the Forlanini procedure. This fact alone, when one considers the percentage of effusions abroad, where for a long time at least the Brauer open method was used, speaks little for the technique as a causative factor.

Exudates may be classified as serous, seropurulent, and purulent, the latter being divided into those showing no organism except the tubercle bacillus and those showing a mixed infection, usually the staphylococcus; the latter are relatively rare, in the work both here and abroad. In my classification I have grouped the seropurulent and purulent exudates under one head. It may be well to state at this time that in all our pus cases the specific gravity was high and a large albumin content was demonstrable, showing without question the fluid to be an exudate rather than a transudate. It would seem that there should be little question at least as to this distinction unless a hydrops could be demonstrated elsewhere in the body.

In all of our series of pus cases, as I will show later, we were able to demonstrate by cultural methods and microscopic examination tubercle bacilli alone in all but three, and two of these showed a staphylococcus, the other patient leaving before a specimen could be obtained; however, owing to the symptoms we supposed this case to be one of mixed infection. Another patient developed high fever, but we could not demonstrate the presence of fluid after repeated examination. Later he left for Colorado and his physician reported that a few days after arrival the presence of a pleural effusion was noticed. The journey, no doubt, was responsible for the formation of the fluid, since I feel reasonably sure that had it been there in an

appreciable amount we should have detected its presence.

The effect of effusions is open to discussion. Certain writers (von Muralt, Koniger) believe that they have demonstrated the presence of antibodies in the exudate and also in the blood stream, and attribute the beneficial effects noticed to this biochemical reaction. However, I fail to see why we should look further than the mechanical effects which, in my opinion, seem to explain everything. It is a conceded fact that in very unfavorable cases of tuberculosis antibodies can me demonstrated in the blood, but these same patients die of their disease, while in many favorable cases the presence of such bodies cannot be demonstrated, and yet those patients recover. Taking now the fundamental idea in the production of pneumothorax, we agree that it is the absolute rest of the lung by the application, so to speak, of a gas splint, to all intents and purposes the same as a plaster cast on a tuberculous knee that produces our results. Why then, when we substitute fluid for gas, should there be any difference in the outcome? As a matter of fact the presence of fluid slowly absorbed lengthens the intervals between the filling, which in itself is to be desired. However, we must admit that the complication is undesirable, highly disagreeable, even dangerous, and the slight advantages gained do not counterbalance the disadvantages.

Many authors mention the diminished absorption of nitrogen and a stiffening of the mediastinum, which, of course, would allow of the possibility of higher pressure without danger of a pushed-over mediastinum and a disagreeable downward pressure on the abdomen. These high pressures even under such conditions are, however, to be discouraged.

Added to this we have noticed in a few cases, after absorption of the fluid, a shrinkage of the affected side which is no doubt due to pleural thickening and the formation of adhesions, together with a certain amount of fibrous deposits on the exudate. The one possible advantage to be gained from this, I believe, is the ultimate tying down of the diseased lung for life; in other words, we have established a continuous compression even after the absorption of the gas.

Now relative to the treatment of these conditions. In the common serous exudates I believe interference is contraindicated so long as the effusion is producing no pressure effects or is showing no tendency to absorb and thus glue the pleural surfaces together; when if pneumothorax is to be continued sufficient gas should be given to insure separation of the surfaces. The danger of repeated tapping lies in the chance of possible infection. Here we have an excellent culture medium, and a single virulent organism carried in on the needle would be sufficient to produce an army of workers in a short space of time.

In the pleural effusions showing only tubercle bacilli it is our custom to aspirate as fast as a sufficient amount is formed, and if there is a tendency to thick pus we introduce a 2 per cent. formalin and glycerin solution. The number of aspirations varies in the different patients, so no hard and fast rule can be made, some forming very rapidly and other very slowly.

In the mixed infection cases we have tried aspiration with the introduction of formalin and glycerin solution and pursued a policy of watchful waiting, only to find that ultimately it became necessary to put in drainage and to leave a discharging sinus. In the majority of all exudates the positive pressure causes more annoyance than the same pressure before exudations take place. Usually, however, this symptom as well as the fever incident thereto can be controlled by keeping the pressure about neutral or slightly negative. The entire treatment can be summed up in the one word, conservatism, with the exception of the mixed infection where radical surgical interference is indicated.

The ultimate outcome of all fluid cases, except mixed infection, I consider good even though showing a purulent exudate containing only the tubercle bacillus. Of course the length of time and behavior of the patient differ. I have seen large exudates give absolutely no symptom and small ones cause great annoyance. I have seen pus develop to such an extent that the pleural cavity was half filled with a dirty green fluid, and the patient exhibited no fever or untoward symptoms of any kind. Then I have seen small amounts of pus call for frequent aspirations to relieve marked pressure symptoms and high fever. A certain percentage of patients after two or three aspirations develop no more fluid and have an uninterrupted recovery, while a few have been repeatedly aspirated for months with no apparent change in their condition. Some of our pus cases have recovered perfectly; others, although still under treatment, are giving no cause for apprehension, while the mixed infection cases have been drained, leaving a discharging sinus. One of these patients is running a normal temperature and going to meals, having gained her former weight and looking perfectly well, while the other is still confined to bed after four months with what I consider a grave prognosis. In all the cases we have had no fatality. I believe it is the consensus of opinion that many of these patients may be subject to exudates for varous periods up to three years, and yet when the temperature returns to normal they can enjoy a fair degree of health with the prospect of ultimate recovery.

Serious as this complication may be viewed from an unprejudiced standpoint we should not be deterred from the use of artificial pneumothorax where it seems to be indicated. On the other hand, conservative men, and I like to consider myself one, will hesitate to induce a pneumothorax until they have given a patient a fair trial on the usual sanatorium routine. To use the procedure in early cases I believe to be a grave error, unless the disease shows a progressive tendency. On the other hand, the percentage of pus cases showing the tubercle bacilli is so small, and the percentage showing mixed infection pus so much smaller, that we can consider the complication a negligible quantity where artificial pneumothorax is indicated.

I will now outline briefly in the following table the results of the work of Dr. A. G. Shortle and myself at the Albuquerque Sanatorium, covering a period from May, 1912, to May, 1915:

Total number of patients operated upon, 110.

Total number of fluids, 32.

Percentage of fluids, 29.09.

Total number of fluids becoming pus, 12.

Total number of pus cases showing tubercle bacilli, 8.

Total number of pus cases showing mixed infection, 4.

Percentage of pus cases, 10.9.

Percentage of pus showing tubercle alone, 7.27.

Percentage of pus showing mixed infection, 3.63.

Now taking out the one patient that left for Colorado Springs, mentioned above, and the patient who returned home before a culture could be obtained, we have but two, or a known percentage of 1.81 mixed infection exudates in our series, one of these being the result of a spontaneous pneumothorax from which, of course, the mixed infection was produced.

To be perfectly fair also with respect to serous exudates, I can say that six of these patients showed an effusion before an attempt was made to produce an artificial pneumothorax. That reduced the total number occurring after the production to 26, or a percentage of 23.63. However, if we take those patients who have been under treatment for a year or more, the percentage will run over 65, thus bearing out the report of other observers who have been working for some time, that the longer we have these patients under observation the more effusions we encounter.

In a careful search of foreign literature I find in a series of 700 cases purulent exudates in 56, or 8 per cent. Out of this number two showed mixed infection, or 0.28 per cent., leaving 54 with pus showing tubercle bacilli alone, or a percentage of 7.71.

In an endeavor to obtain an average of results of men working in America I wrote certain physicians whom I knew to be following this line of treatment. I received replies from nearly all, but in the majority of instances they were very indefinite. Some had kept no accurate record of patients treated, while a few saw the patients only for one or two fillings, then turning them over to the home physician for further treatment. However, as far as possible, I will tabulate the results of this inquiry.

	Number	Fluids	Pus	Mixed
G. B. Webb	103	13	4	0
Ethan A. Gray	135	18	2	0
Mose Collins	16	1	1	0
Silvio von Ruck	65	12	2	1
Earl H. Bruns	28	11	1	0
Herbert King	57	6	0	0
H. Schwatt	70	12	3	0
Ralph Matson	32	6	2	0
C. L. Minor	51	10	2	2
Total	557	89 or 16 per cent	16 or 3 per cent	3 or 0.54 per cent

Walter Holden and Mary Lapham give only the percentage of cases showing effusions. These are respectively 11.5 and 20. Holden cites one mixed infection due to spontaneous pneumothorax, while Lapham mentions empyemas as a complication in her series. It is interesting to note that Lapham's percentage is about the same as ours, and she has been using the method for five years. Our experience covers a period of over three years, while the majority of American reports are for much shorter periods, and this, I am convinced, accounts for the lesser number of effusions. Gray states that he believes all cases show some fluid, but reports only those in which it could be easily demonstrated. I know from experience that the *x*-ray will show many small effusions that would be overlooked in ordinary physical examination.

J. Woods Price states that in their series of over 100 cases they have had about 50 per cent. effusions, some becoming purulent but none showing mixed infection. From my own experience and from having closely followed the literature, I believe that the infections with pus organisms and with the tubercle bacillus must be looked for from within. That technique plays an important rôle there can be no question, but when one adheres closely to the technique for major operations it seems hardly possible that the fault could lie there. On the other hand, if this were so the effusions should, in the natural course of events, all become purulent, while we know that we encounter mixed infection only in a very small percentage of cases.

Bonny reports three instances of pyopneumothorax resulting from a spontaneous rupture, and states that he is convinced that the infection comes from within. This is also the opinion of Floyd of the Massachusetts General Hospital of Boston, and Bruns of the U. S. Army Sanatorium at Fort Bayard, N. M. Bruns further states that he believes that the infection is purely accidental and likely to happen to any operator, no matter how careful his technique. Webb believes that the infection can be from without or within, which, of course, must be granted until we have stronger proof than at present. Murphy and Kreuscher claim to have had no pleural effusions, and state that if they should occur they would be due to causes other than the pneumothorax treatment. This coming from a man who was one of the first to use this method sounds amazing, especially in view of the vast horde of workers in this special field of tuberculosis endeavor. I am at a loss to account for his phenomenal results and shall await an opportunity to learn how such a disagreeable complication is to be avoided.

Holden is convinced that the technique plays a very important rôle and is sure we would have fewer pus cases if we watched the administration of gas more closely, his criticism being that we are too prone to run high pressures. To offset this argument I can say that it is a rare occasion in which we ever bring the pressure to more than neutral, and yet we have had the average percentage of effusion cases.

Gray believes that nitrogen is a sufficient cause for the effusions, and he deplores the frequent aspirations of such fluids, never interfering unless to relieve an embarrassed heart or opposite lung. He mentions the use of a blunt needle for the first operation of the infected lung. There can be no doubt that this point is wisely taken, for one can easily see the grave possibility of infection after such puncture. Shortle believes in frequent aspiration of fluids and the refilling with gas in order to avoid a possible rapid absorption and gluing together of the pleural surfaces, thus prohibiting the further continuance of a pneumothorax. I believe there is a happy medium to follow and would advise that a careful watch be kept, interfering only when there seems to be absorption of the fluid taking place.

From the foregoing statements and tables it seems to be demonstrated first that, given sufficient time, fluids develop in the majority of patients.

Second, that a certain percentage of these fluids become purulent.

Third, that the majority of these purulent effusions are due only to the tubercle bacillus.

Fourth, that a certain small percentage show organisms other than the tubercle bacillus, constituting an empyema.

Fifth, that unless producing pressure symptoms

and high fever serous effusions and effusions showing tubercle bacilli should be left alone. One should aspirate as little as possible.

Sixth, that all mixed infection exudates should receive proper drainage and be treated by radical surgery.

Seventh, that the slight advantages occurring from exudates are offset by the many disadvantages.

Eighth, that as the percentage of pleural exudates is so small we can consider the complication a negligible factor where artificial pneumothorax is indicated.

RELATION OF NASAL SYMPTOMS TO ENDAMEBIC INFECTIONS OF NOSE AND MOUTH.

By ALEXANDER C. HOWE, M.D.,

BROOKLYN, N. Y.

ASSOCIATE LARYNGOLOGIST OF THE JEWISH AND METHODIST EPISCOPAL HOSPITALS.

A CERTAIN group of nasal symptoms has for a long time baffled all attempts to relieve them. The clinical picture is a composite of a distinct group of symptoms; sudden onset, sneezing, watery nasal discharge, stuffiness of nose, postnasal rawness and sense of chilliness. The attack may last a few minutes or an hour, and clear up as rapidly without sequelae. The subject of these attacks is usually depressed and rarely feels "fit," or in a condition to do efficient work. Between the attacks the nasal passages rarely feel clear and comfortable. These attacks are usually associated, by the subject, with an exposure to draughts. He feels that he is subject to "colds." He usually associates the shortness of the attack and its sudden and complete clearing up to some care or remedy he has learned to use.

For the sake of brevity in reporting the following cases, I have called these attacks paroxysmal or abortive coryza, as they simulate an acute nasal infection, but lack the prodromal and clearing up features. The onset promises an acute coryza, but always aborts. The frequency and length of these attacks are modified by intranasal conditions, but are not caused by deformities or chronic infections, as a large number of my cases had no intranasal defects, or the symptoms continued after the nasal defects had been corrected. In the first and second group of cases reported, the nasal conditions were good or were made good, and yet the attacks of abortive coryza continued. In the mouths of all the cases reported, a more or less entensive pyorrhea alveolaris existed. Endamebae were found in the pus pockets between the gums and teeth, and in some of the cases the endamebæ were also found in the nasal discharges or secretions. That they were not found oftener in the nares in the earlier cases was due to the failure to recognize that the endameba in the nose differs radically from the endameba *buccalis* of the mouth. The *Endameba nasalis* resembles the *Endameba histolytica* of the intestines. It differs, however, in being larger, more irregular in outline, and in other general characteristics. Apparently the habitat affects the appearance of the endameba. Again, it is often difficult to secure a specimen from the nose near the focus of infection; hence, it is possible that failure to find the endameba is due to a disintegration of the endameba before it comes within reach.

The following is a report of a number of typical cases, their treatment and the results:

CASE I.—Male, age 40; large, powerful, and robust. Gave a history of recurrent nasal attacks. The first attack occurred during an auto ride three years ago in Cuba. It was perfectly typical of every attack since and just as severe. While riding at night, he had the sensation of the onset of a sudden cold in the head. The attack was characterized by frequent and violent sneezing, free watery nasal discharge, and rapidly increasing intranasal pressure. The onset was so sudden and severe that he was obliged to turn about and slowly return to his hotel where he felt very ill for about three hours. Next morning he was entirely free from sequelæ. About a month later he had another attack. From then on, the attacks increased in frequency until they occurred several times a day. At the time of his first visit to me the attacks usually began soon after rising, or after breakfast, and occurred at irregular intervals, but never during sleep at night. They would last from a few minutes to an hour, and would incapacitate him from business, or from driving his auto. He said that he was subject to "colds," and had frequent chilly sensations. Although robust, he was constantly on the alert to protect himself from draughts or getting "chilled."

Examination showed a rather narrow nose, perfectly normal except that the mucous membrane seemed reddened or superficially irritated. There were no pressure areas, and no nasal discharge. Nasopharynx was normal. The symptoms suggested a recurrent, anaphylactic condition, and all animal proteins except milk and cheese were excluded from his diet.

I have used "anaphylactic" in a somewhat broad sense to express the quality of the symptoms, which do not tally with those of a definite poisoning by bacteria or their products; nor do they approximate the severe type shown in patients sensitized to horse serum. They suggest, rather, the condition known as "protein sensitive." But as this is too cumbersome an expression, "anaphylactic" as used hereafter must be understood to indicate, rather than describe, the effect of the unknown amebic poison.

There was no relief at the end of ten days. A nasal and mouth smear was then made. The mouth proved positive for entameba, but the nose was negative. Injections of emetine were begun, and he was referred to his dentist for surgical treatment. From the first the attacks diminished in frequency and severity. At the end of six weeks, they had ceased. Two months later he reports entire freedom from any attack, and from the physical depression that was almost constant.

CASE II.—Female, age 35; slender, not robust. For years had recurrent attacks of sneezing, nasal stuffiness, and watery discharge, slight chilly sensations, and pharyngeal rawness. These symptoms usually disappeared as suddenly as they came, and rarely lasted more than half an hour. Nasal examination showed no abnormality or discharge, except areas of superficial irritation in the mucous membrane. Endamebæ were present in the mouth, but not in the nasal smear. Two months' emetine treatment and the necessary dental surgery resulted in entire cessation of the attacks, and an increase in the feeling of well-being.

CASE III.—Male, physician, age 50; healthy except for a persistent tinnitus, a susceptibility to slight head colds, and short but sharp attacks of nasopharyngitis. Several nasal operations, some years previously, had put the nose in a good anatomical and functional condition except for a tendency to stuffiness in the left nasal passage. Recurrent attacks of paroxysmal coryza and nasopharyngitis aggravated the tinnitus. A condition of depression and of lack of initiative frequently existed. These abortive attacks of coryza were typical of those described above. Because of the increasing tinnitus, relief from the nasal condition was sought, but with only temporary success. The case was submitted to me without examination, and from the clinical picture alone a diagnosis of endamebic infection was made. Later examination of nasal and mouth smears showed endamebæ in both, although the teeth gave no evidence of pyorrhea.

Surgical treatment of the mouth and injections of emetine cleared up the nasal stuffiness, stopped the coryza attacks, lessened the tinnitus, and increased the sense of well-being and general efficiency in his professional work. The improved conditions continue to the present time of writing.

CASE IV.—Male, age 42; robust and vigorous. A submucous operation two years ago had greatly relieved a very bad nasal condition, but a sense of nasal discomfort with frequent recurrent, abortive attacks of

coryza, and a feeling of profound depression persisted. The anatomical relations resulting from the operation were all that could be desired, but the nasal stuffiness continued, although he seemed to have a normal amount of breathing space.

Nasal smears were negative. Mouth smears were positive, and the teeth in bad condition. The surgical treatment of the teeth and emetine injections rapidly and completely relieved the nasal attacks and symptoms. The depression and toxemia cleared up, and interest and efficiency in his business increased. At the date of writing he reports a radical change in both his mental and physical condition. The relief is absolute.

CASE V.—Male, age 45; neurotic and in a bad neurasthenic condition. Sense of suffocation prevented normal sleep for days. A badly deflected septum and hypertrophied turbinals occluded both nasal passages. Intranasal operations gave him fairly normal conditions, and yet his attacks of paroxymsal coryza, nasal stuffiness, susceptibility to colds, chilly sensations, and neurasthenic conditions did not clear up. A bad pyorrhea alveolaris existed. Smears for endamebæ were positive for both nose and mouth. All nasal and neurasthenic symptoms gradually cleared up under proper dental surgery and emetine treatment. The emetine was given by mouth.

CASE VI.—Female, age 32; came under my care for an acute infection of accessory sinuses. After the acute attack cleared up I learned she was subject to frequent abortive attacks of coryza, and was in a physical condition that handicapped her greatly in her work as a teacher. The nasal cavities were normal, and the postnares negative. The pyorrhea alveolaris was very advanced. Several teeth had virtually fallen out, and four were very loose. The gums were badly receded. Endamebæ were found in both nose and mouth. Under emetine treatment the nasal symptoms rapidly cleared up, and the general condition improved, but if the emetine treatment was stopped, she gradually reverted into her former condition. Under the dental treatment which she received, there was slight improvement in the condition of the mouth. The lack of skilled and intelligent dental treatment of the mouth accounted for the failure in this case.

Twenty-three cases of the above type were treated. All but three were entirely relieved of the nasal and general symptoms described, and have remained so to the present time. The three cases that slowly developed the former symptoms again after the emetine treatment was discontinued were all cases in which there was little or no improvement in the mouth. This in each instance was due to some fault with the dental surgery. The permanency of the results depends entirely upon the elimination of the pus pockets between the gums and the teeth. So long as they continue reinfection occurs, and the chain of symptoms gradually returns.

The following series are all cases of abortive or paroxysmal coryza, accompanying persistent chronic accessory sinus conditions that were not relieved by various sinus operations.

CASE VII.—Female, age 62. Had repeated attacks of endocarditis and polyarthritis since eighth year of age. Two years ago she came under my care for severe pain over right frontal sinus and profuse purulent discharge from the right nares. She had recently recovered from one of her many attacks of acute infective arthritis. Examination showed an extensive necrosis of the anterior ethmoidal cells and a profuse thick creamy discharge from the frontal sinus on the right side. This condition had existed eighteen years. A Mosher operation relieved the pain, but although excellent drainage from the frontal had resulted from the operation, the discharge continued profusely in spite of all treatment. This past winter she developed septic appendicitis, neuritis of the left arm, polyarthritis of severest type, and a severe toxemia. Four months ago we found both nasal discharge and mouth secretions filled with endamebae. The mouth conditions were very bad. Only roots surrounded by pus pockets remained. Her feeble condition and pain made dental surgery impossible. Under emetine injections alone the discharge from the frontal sinus rapidly diminished, and within a month the vault of the nares was practically dry. From that time to the present the nares have remained clean and dry, and the general condition has greatly improved. The general septic infections probably came from the pyorrhea alveolaris as well as the focus in the frontal sinus.

CASE VIII.—Male, age 35. Came to me for examination four years ago. Gave a history of having a pansinusitis on the right side for the preceding two years. The pain and toxemia incapacitated him for his work much of the time. The drainage resulting from several previous operations was very unsatisfactory, and the irrigations he received once or twice a week were very painful. He refused operation, and returned home to a distant city where the treatment was continued, and the infection extended to the left side. Two months ago he came to me again. He had frontal and occipital pain, and both nasal vaults contained polypi bathed in thick pus. He was septic, and mentally and physically depressed. Nasal and mouth smears were filled with endamebae. Ten days before a double operation for exenteration of ethmoids and drainage of frontal and sphenoids was performed, emetine treatment was instituted. Almost at once the quantity of pus and the intranasal pressure diminished, and the polypi shrank as they always do when discharge lessens. At the end of ten days the operative field was a very different proposition than before the emetine treatment. The postoperative discharge, local reaction, and polypoid condition were far less than is usually the case after similar operations. I regret that sufficient time has not elapsed to report the ultimate result, but the emetine treatment simplified the operation to such an extent that a report of the case is justified.

CASE IX.—Female, age 27. Has a punched-out ulcer on the inner side of the anterior end of the right inferior turbinate. She also has a curious skin lesion which, although it has existed for years, like the nasal ulcer, suggests a specific origin. Wassermann was returned negative. The ulcer has been under the care of a rhinologist for a year without healing. At the time of her visit to my office, the ulcer was 5/8 inch in diameter. Smears from ulcer and mouth both contained endamebae. A radical change in the appearance of the ulcer began at once after emetine injections, and healing progressed rapidly. Ulcer entirely healed in two weeks.

CASE X.—Female, age 76. Severe parietal pain two years ago. Relieved by exenteration of left ethmoids. Recovery uneventful, but a slight streak of pus appeared now and then in the left nasal vault. Pain has had a tendency to return several times the past year. No cause could be found. Nasal smear proved positive, mouth smear negative, probably due to lack of teeth. Nasal discharge and parietal pain rapidly cleared up under emetine by mouth and have remained so the past four months.

CASE XI.—Male, age 37. Came under my care for acute empyema of left antrum, and frontal. Operation rapidly cleared up the antrum, but the frontal continued to discharge freely, although free drainage had been established. Mouth smears positive of endamebae; nasal, negative. Emetine injections and dental surgery improved the mouth condition. The frontal discharge diminished about 50 per cent. He has recently developed a myocarditis, and the frontal still discharges moderately.

CASE XIII.—Female, age 28. Five years ago I exenterated the ethmoids, and opened the sphenoids, antrum and frontal on both sides to relieve the unbearable pain of an acute pansinusitis. The operation relieved the pain, but a more or less slight but constant nasal discharge continued. Repeated examination showed no explanation. Several times a year she contracted a severe grippe infection of the nares. These attacks made her very ill, and caused great local pain. She also had frequent attacks of abortive coryza. She was constantly miserable, depressed, and unable to assume any responsibility. She consulted me recently for another acute nasal infection. This cleared up under the usual treatment, but left her in the same unsatisfactory health. Nasal and mouth smears were thick with endamebae, although there was no evidence of pyorrhea. As she was within two weeks of her accouchement, it did not seem advisable to give the emetine treatment. The case is reported as it is typical of the persistence of nasal discharge in spite of good drainage when andamebae are present.

The above are part of a series of ten cases that have come under my care since I began to study the relation of endameba to the persistent discharge from the accessory sinuses in spite of excellent surgical treatment and excellent resultant drainage. Six cases cleared up rapidly under emetine treatment and remain so at the present time. Two cases gave unsatisfactory results for reasons I am unable to determine. Cases VIII and XII cannot be classified yet.

The following cases all had typical recurrent attacks of abortive coryza and general malaise that suggest endamebic infection of nose, mouth, or alimentary tracts. Besides these specific symptoms all suffered from some general condition that was relieved by the effort to clear up the nasal conditions.

Case XIII.—Female, age 21; slender, not robust. Referred to me latter part of 1914 for acute mastoiditis. Simple mastoid operation, followed by uneventful recovery. Referred to me again six weeks ago for a so-called neuralgia of upper and lower maxilla on both sides. The paroxysms of pain were so severe that sleep was impossible without an opiate. The efforts of her dentist and physician were without effect. The attack had lasted two weeks when I first saw her. Intranasal examination and transillumination gave negative findings. The teeth had no cavities. One lower and three upper teeth had small pus pockets under the gums. Smears were strongly positive. Endamebæ were the only etiological factor that could be found. The gums were perfectly normal except for these small pockets. It did not seem possible that the severe pain could be caused by this condition. For want of a better trail to follow, emetine injections were given and the paroxysms of pain at once began to lessen and to recur at longer intervals. Within a week the pain had entirely stopped and remained so.

Case XIV.—Male, age 67; Englishman. Frequent attacks of abortive or paroxysmal coryza, very nervous, depressed, apprehensive, heart and sternal constriction and general toxemia. Had a blood pressure of 217, and a mouth full of suppurating roots. Treatment to reduce blood pressure and stimulate renal excretion failed to clear up the chief symptoms. Nasal and mouth smears were strongly positive. Emetine treatment was added to his general treatment. The result was that the depression, the toxemia, and sternal and precordial sensation of constriction were emphatically relieved as well as the nasal condition.

Case XV.—Male, age 57. Two severe attacks of heart block, one a year and a half ago and the other about a year ago. Had specific nasal and general symptoms of endamebic infection. Consulted me for tendency to recurrent abortive colds in head. Nasal examination showed left posterior exostosis without much pressure, and a superficially irritated mucous membrane. The mouth showed an advanced pyorrhea alveolaris. Pus pockets were frequent. Two of the roots of one molar were free in the mouth. Three other teeth were very movable. He had also had severe precordial distress and digestive disturbance almost constantly since his last attack of heart block. Nose and mouth smears were positive. Under emetine and dental surgery the tendency to colds in the head, precordial distress and fear to eat disappeared.

Eight other cases of which the above are typical have come under my observation where persistent general conditions have cleared up under the emetine treatment given for relief of nasal conditions.

The exact relation of endamebic invasion of the nose, mouth, or alimentary tract to local and general symptoms is difficult to determine. That there is an etiological relation I am positive. Are the symptoms due to the toxemia from the bacteria that feed upon the material eroded by the endamebæ or to an anaphylaxis from the endamebic excreta? If the symptoms were due to bacteria, emetine would not clear them up so rapidly. The fact that there is such a radical and rapid relief of the symptoms would indicate the excreta of the endamebae are the cause rather than the proteins of dead endamebæ. Otherwise, the rapid destruction of the endamebæ by emetine would intensify rather than immediately relieve the symptoms. If the symptoms were due to endamebic excreta they would be anaphylactic rather than toxic.

The nasal symptoms of abortive coryza simulate the anaphylactic symptoms of pollinosis, and the accompanying physical depression and lack of feeling "fit" are distinctly anaphylactic. The sternal constriction and precordial distress as seen in several cases are frequently seen in severe anaphylaxis.

In pyorrhea alveolaris the endamebæ erode off the blood-vessels, the lymphatic spaces, and, when the disease progresses far enough, the bony edge of the alveolar process. This opens up direct communication with the lymphatic and vascular circulation as well as the bone channels. A tooth rests on an elastic cushion at the bottom of its socket. A pressure of 200 to 400 pounds is exerted on the molars during mastication. This forces onward the fluids in the lymphatics and vessels in the cushion. With the release of the pressure the vessels fill again, and the same process takes place. By this means bacteria could be forced into the lymphatic or vascular circulation. The endamebic excreta could be absorbed in the same way and cause anaphylactic symptoms as easily as the proteins of pollen are absorbed through the mucous membrane of the nose and, in sensitized subjects, produce pollinosis.

The cases reported represent about 20 per cent. of the cases found to have endamebic invasion of the mouth. The reported cases all had characteristic abortive or paroxysmal attacks of coryza as well as anaphylactic symptoms. That the rest were free from these symptoms is due probably to the fact that they had not become sensitized. All people inhale pollen, but only those sensitized develop pollinosis.

Summary.—A characteristic group of symptoms, for brevity of reporting cases, called paroxysmal or abortive coryza, is frequently associated with the presence of endamebæ in the mouth or nose or both.

The chronicity of certain nasal symptoms and sinus discharge is frequently maintained by the presence of endamebæ at the source of the irritation or discharge.

The nasal symptoms and some coexisting general symptoms are due to a toxemia, or to an anaphylaxis caused by absorption of the proteins from the endamebæ.

The specific action of emetine on the endamebæ makes it possible to relieve a very large proportion of cases sensitized to their proteins.

For the laboratory work in connection with this study, I am indebted to Dr. S. J. Wilson.

Homogenized Olive Oil and Fat-Free Milk.—Maynard Ladd states that in general, the results obtained in the use of homogenized olive oil as a substitute for cow's fat in cases of difficult feeding are such as to warrant the hope that it will prove a safe and valuable means of administering fat in the so-called cases of "fat intolerance." Its use will not, however, relieve the physician of the necessity of intelligent application of the principles of modification and adaptation of the food to the individual requirements of the infant.—*Archives of Pediatrics.*

OBSERVATIONS ON THE USE OF PITUITARY EXTRACT.*

By SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF DISEASES OF WOMEN, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

A WONDERFUL gland is the hypophysis. From earliest infancy it is intimately associated with the growth and development of the body, producing variations from the state of a dwarf to the stature of a giant. Its relation to the genital tract is most important. After adolescence it may produce acromegaly or that peculiar state in women known as dystrophia adioposogenitalis. Its most startling and specific relationship is to be found in the influence which the posterior lobe has on labor.

Why labor occurs at the tenth lunar month, usually within an accurate range of time, we do not know. We do know that in all probability this posterior lobe of the hypophysis through its secretion stimulates and influences uterine contractions. We know the changes which are produced in the hypophysis cerebri during pregnancy, changes which never entirely disappear, but do not yet know what initiates the activity of the secretion of the posterior lobe.

When an extract of the pituitary gland is injected during labor it stimulates uterine contractions, increasing all the various powers of the uterus to such a degree that we have a perfect right to say that the secretion of this gland is responsible for labor. This secretion, injected before labor has begun, has little influence except to produce a painless contraction. What new relation between the various glands occurs just before labor or what inhibitory influence is released, or what new secretion is introduced is as yet not definitely known.

When we inject pituitary extract, we are injecting a secretion normal to the body. When we inject it during labor, let us take it for granted that we are simply increasing the amount of this secretion, and hence simply bringing its activity up to the maximum that is advisable. The most that it does is to make the uterus behave as it does in the most typically normal forms of labor. It makes the uterine contractions effective. The patient has pain, the usual amount of pain is often increased, but the patient has genuinely valuable uterine activity. There is no toxic effect. There is no injurious influence on the patient's general systemic state.

The drug is put up in ampules. A hypodermic of a complete ampule produces a too forcible uterine contraction. A third or half an ampule is sufficient at any one time. The effect wears off at the end of a half an hour. If a patient in the preliminary stages has regular or irregular pains or discomforts, and is actually in the first stage of labor, even though it be extremely sluggish, injections of pituitary extract prove them to be real labor preliminaries by changing them to regular forceful rhythmic contractions.

Now with these facts before us it is a very simple thing to decide as to the value of pituitary extract, when it should be used, and how it should be used. I may put the statement in a few words. Whenever at any stage of labor, progress is slow (when conditions are normal), whenever labor pains are ineffectual (when conditions are normal), whenever labor pains become sluggish, or cease, or uterine atony supervenes (when conditions are normal), pituitary extract, in single or frequently repeated doses, makes the case behave like a normally progressing labor.

Now, what is meant by the statement, "when conditions are normal"? By this is meant that the position and the presentation and the relation between the fetal parts and the bony pelvis are such that a live baby may be expected with a fair degree of certainty.

In the first stage in primiparæ the head must be firmly engaged in and through the brim, and the head must be well molded. If the first stage proceeds too slowly under such conditions pituitary extract is indicated. After the cervix is completely dilated and the membranes are ruptured, and the well-molded head is through the brim, pituitary extract may and should be given when progress is slow. These observations are directed particularly to the labor in a primigravida. In the third stage pituitary extract aids in the expulsion of the placenta, although for this purpose I am accustomed to use ergotole and the Credé method.

In discussing the first stages of labor, the attention of most men is fixed upon the elements of dilation of the cervix. Very little stress is laid upon the fact that the head *must be firmly engaged in the brim and must be gradually molded so that it* may make its way through the bony inlet. If the head is molded, after being firmly engaged, as labor pains continue, the element of dilation of the cervix itself can more readily be controlled than if the reverse were the case. We are here confronted with a condition very much like that in dry labor, where the molding of the head and its gradual propulsion by the uterine contractions serves to dilate the cervix even if more slowly than were the membranes still intact. Hence, an all-important factor in the use of pituitary extract is that we must be sure of our proportions. We must be sure that the head is fixed and molded, and can pass through the brim without very great effort. If this is the case, and if then the cervix dilates slowly, or the further propulsion of the head goes on too slowly, the use of pituitrin in small doses will exert the most marked hastening effect upon the progress of the labor.

Pituitrin is very much the same as gasoline to an automobile. The more steadily we feed the automobile with the least amount essential to each speed, the greater is the effect. Pituitary extract, granted that all other conditions are normal, will aid the first stage, and will benefit markedly the propulsion of the second stage in primigravidæ. In multiparæ the effect is most remarkable in many cases, even when the head is not engaged in the brim, when the previous history shows that labor had progressed normally, and when there is no disproportion between head and pelvis bones. Labor is not infrequently completed; that means dilatation of the cervix, rupture of the membranes, expulsion of the child, in fifteen minutes after the first or second injection of pituitary extract.

In women who have already had children and in whom there are no bony malformations I use pituitary extract as soon as well recognized labor pains are present, and if the pains are irregular and not definitely diagnosed as true labor pains, pituitary extract is used to make this diagnosis. My experience has been that in multiparæ, with

*Read before the Hartford Academy of Medicine, June 7, 1915.

the aid of pituitary extract, the average duration of labor is two hours after I have reached the bedside.

Now, what has pituitary extract done for the obstetrician who uses it in the way I have mentioned above?

It has given him the opportunity of determining whether the so-called false labor pains are false or true ones, and they are often true ones. It has enabled him to shorten the duration of labor in primigravidæ and in multiparæ to a most decided degree. It has cut down the need for the application of forceps to such a degree that their use is scarcely ever indicated except in emergencies. It has almost entirely removed from the field of consideration long and protracted labors due to uterine inertia (emphasis on "due to uterine inertia"). It has given a much greater degree of certainty against the probable or possible occurrence of postpartum hemorrhage.

Let me say a few words about cesarean section. As soon as the incision in the abdominal wall is begun the patient receives a hypodermic of pituitary extract, one ampule. As a result, as soon as the fetus and placenta and membranes are delivered the uterus contracts so decidedly that the sewing is readily accomplished, the loss of blood from the wound surfaces is absolutely nil, and the bleeding from the uterine lining is remarkably slight. I repeat these hypodermics in similar doses for several days after the operation.

In abortions and miscarriages pituitary extract has no wonderful action in contracting the uterus, and I do not rely upon it entirely, using it and ergotole alternately during the curettage or the emptying of the uterus. I use both alternately to secure a proper involution after emptying of the uterus. With the ovum still intact, I rely on the packing of the uterus and vagina, and then use pituitary extract and ergotole alternately.

Of what value is pituitary extract to the gynecologist?

I have used this drug in a large number of cases of menorrhagia and metrorrhagia not dependent on growths or overgrowths in the uterus. I have given one ampule daily, or on alternate days for weeks at a time, and have rarely failed to benefit the patient.

The Dührssen operation is not infrequently followed by a tendency to menorrhagia, due in all probability to congestion. These patients are almost of a certainty relieved of their annoyance by the aforementioned use of pituitary extract.

There is no form of uterine bleeding, except that due to carcinoma, in which the continued use of this medication for six or eight weeks can in any way be productive of harm.

Pituitary extract is supposedly a powerful stimulator of peristalsis, and I have many, many times seen it work wonderfully in postoperative and postpartum cases. In two instances where catheterization was needed at intervals in patients not in the postoperative or postpartum stage the repeated daily use of pituitary extract has aided markedly in the restoration to the normal.

Some patients are a little sensitive to this drug, a slight pallor of the face and a little coldness of the extremities resulting which wears off at the end of fifteen minutes; their occurrence is by no means the rule, but rather the exception. In the obstetric cases I have never seen even this annoyance.

134 West Eighty-seventh Street.

AN UNUSUAL CASE OF MASTURBATION.

By J. ALLEN GILBERT, Ph.D., M.D.,

PORTLAND, OREGON.

The object of this brief report is to put on record a case which seems sufficiently striking to justify its being reported. The following history was obtained from his parents.

D. H——, a boy 10 years of age, has masturbated ever since he was two and a half years old. At this age it was a definitely established habit though the history extends back even farther than that—"practically to birth"—as one parent expressed it. At the age of five he was a physical wreck due to the peculiar method of masturbating. Resting on his head and feet forming an arch of the body with the abdomen downwards, by a peculiar longitudinal rocking motion of the body he obtained his satisfaction. The hands were not used at all. This rhythmical motion so shook the bed and room that it would wake the parents. At the completion of the process he would be more or less exhausted and covered with a profuse perspiration. He has been known to accomplish the act as often as twelve times in one night. His indulgence is not confined to the night but he resorts to his habit as often as opportunity will permit during the day. At the age of five he learned to accomplish the act by lying on his back and using the hand to rub the parts. From that time he gained in physical strength and though he was 3½ inches under normal height and 13 lbs. under normal weight for his age he looked rather well and rugged. At four years of age he committed rape upon a little girl of about his own age on a country road. At the age of 9 he did the same to a little girl slightly older than himself. At this time he took her back into some bushes to accomplish the act. After questioning the boy, with caution not to give him any knowledge of anatomy that he did not already have, I could not convince myself that there was real sexual intercourse. He is not strictly truthful regarding things relative to his habit and he may have intentionally misled me, but his answers seemed to indicate that he did not have full knowledge of the difference of sex. I purposely avoided any questions or remarks which might reveal to the boy the true method of sexual intercourse provided he were still ignorant of it. He did on one occasion, however, make the proper distinction and used the vagina of a bitch for sexual gratification. It has been impossible for the family to keep any pet animals. Cats, dogs, and his small brother two and one half years old were all used for the gratification of his habit whenever opportunity allowed. He could not be left in the presence of his brother for a moment without rubbing him till the parts were all inflamed. On one occasion he was found on the back of a fierce bull-dog in the neighborhood that everybody was afraid of. Shortly before he came under my observation the mother sent him four blocks away to mail a letter; as he remained longer than necessary she went to hunt him and found him behind a woodshed with a little girl. An incensed neighborhood had made it expedient for them to move several times within the year previous to their coming to me.

He has had only a year and a half schooling because he could not be kept in school on account of the fact that he spread the habit right and left among the children. During earlier years he showed no signs of shame whatever, indulging his habit in the presence of his parents without hesitancy. Of later years he sought privacy though he still discussed it apparently unabashed. At one time in my office I asked him to show me how he did it. Without shame or hesitancy he proceeded to a demonstration which I stopped. His mother was unable to keep any pockets in his pants for he worked holes in them through which to reach the penis and would perform the act in this way without the unsuspecting observer detecting him in it.

All methods the parents and various physicians could devise had been tried without avail. Even tying him down to the bed so that he could not move arms or legs did not prevent him from wriggling the body sufficiently to accomplish his end. The only way to prevent him was by constant watch day and night. For a year they sent him to the country to try absolute seclusion from suggestive surroundings such as the city with its children might afford. While there he indulged his

habit as before, even appropriating the chickens to the accomplishment of his end. The usual medical treatment gave no results. Suggestion failed. Detention in a private sanitarium in Santa Clara, Cal., brought no improvement. The superintendent of the insane asylum at Agnew, Cal., tried various preventive mechanical appliances and local irritants to stop the habit. The superintendent of the State School at Whittier, Cal., advised circumcision and resection of the vas deferens. A Seattle physician also tried various mechanical devises without success. The boy merely used the apparatus to rub against and accomplish his end. Kindness, punishment, including severe corporal punishment, rewards, etc., have been entirely without effect.

The Oregon State School for Feebleminded refused to take him unless he were circumcised and castrated. The father says the boy is a thoroughly good child and obeys in every particular except in reference to this fixed habit. He will not even promise not to do it any more. His only answer to such a request is "I do not know."

In their extremity the parents appealed to the Juvenile Court for advice and help. The court having no means of dealing with the boy referred him to the Society for Charities and Corrections, and they brought him to me. The boy was well nourished and yet underdeveloped, as stated above. He was nervous. Finger nails were bitten off close to the flesh. The foreskin was long and non-adherent. The parents testified to his being bright but he would not play as a child should. If told to build a block house he would build it mechanically in obedience to commands but manifested no interest in building it, tearing it down and rebuilding it. If told to ride his tricycle he would ride it mechanically till allowed to stop. He was polite and refined and showed every evidence of a good home and surroundings.

Circumcision was advised and performed by me on Feb. 22, 1911, not with the expectation of a cure but as a palliative measure. The second day after the operation he indulged his habit as before, protecting the head of the penis in the hollow of his hand and applying friction with the fingers and thumb at the root of the penis. If anything, he seemed to be worse after the circumcision than before, the local irritation probably serving as a stimulus to draw his attention to the parts. The parents had requested both circumcision and castration at the original operation and now urged castration both for the sake of the boy and the protection of the public. They were convinced that as soon as the parts reached development to the point of producing spermatazoa he would impregnate some girl. As yet there was no orgasm. The testicles were still undeveloped. The request for castration presented a problem and accompanying responsibility of no mean degree. I hesitated long, but finally became convinced that it ought to be done both for the good of the boy and the public.

It was not thought that castration would remove entirely the desire for the habit, for it would seem that the difficulty must be central, but on the same principle that castrated kittens, colts, pups, etc., lose almost entirely the sexual instinct if castrated when young the supposition seemed likely that, being castrated at his present age before development of the sexual organs was complete, the habit in the boy might at least be abated to a marked degree and thus protect his nervous system from the ruin which the existing amount of indulgence would seem to make inevitable. Furthermore, the public has rights which should be considered in such a case. This element played no small part in the decision reached.

Not satisfied with my own conclusions on so important an affair, I consulted a number of physicians and a large majority advised that it be done. Realizing that it is easy to give an opinion when the subject under consideration is not one's own personal affair to deal with, I did not rest entirely on the opinion of physicians alone, but appealed to three judges of the courts, the county physician, officers of the Society for Charities and Corrections, and they all felt that it ought to be done. Though the task was an unpleasant one, I finally consented to castrate the boy on the written request of the parents. While in the wash room preparing for the operation the history of the case was presented to two other physicians who were present. These two men raised such a vigorous protest against it that I finally postponed the operation in order to give time for further consideration. During the discussion at this time the father was present and was so affected that he turned pale and prompt removal to the open air barely prevented syncope. For two weeks after the ordeal which was evidently trying to him, he suffered with pains over the heart and was unable to lie on that side.

The case was then submitted to the Portland Academy of Medicine. There was only one dissenting voice. He, a genitourinary specialist, simply said, "I have no opinion to offer, but I have profound respect for a man's testicles."

Dr. S. A. Robinson, who took great interest in the case, took the history of it to the Governor of the State. In his opinion the State had no place to care for such a case, and he strongly advised castration. I then operated on March 20, 1911, and castrated the boy. The small incisions through which the testicles were removed, as well as the scrotum and a large portion of the penis were covered with a flexible collodion dressing to prevent him from infecting the wound should he continue his habit in spite of it. This dressing put him to some inconvenience, but he continued the habit immediately after the operation. During the night of March 24, four days after the operation, he masturbated six times, and during the morning following he accomplished the act seven times before coming to my office. He said that he usually could and did do it oftener in the afternoon than in the morning. The operation seemed to have no immediate effect on the boy. The incisions healed by first intention. While he still continued the habit the father reported on April 15 that more effort was required on the part of the boy to obtain satisfaction in the act. Shortly after this the mother reported that he had gone back to his boyhood method, viz., with his head and feet on the bed or sofa, he formed an arch of the body with the abdomen downwards and then by a forward and backward rocking of the body he obtained his gratification. The hands were not used at all except to steady the body while they rested on the sofa. At one time at my request he proceeded without shame or embarrassment to a demonstration of the method which I interrupted. In rocking the body forward the head was flexed under the chest to such an incredible degree that the impact of the movement brought the occiput of the head against the sofa with such force that he was bald at that point. One really felt that he was in danger of breaking his neck in the process. This method had so developed the posterior muscles of the neck that when he stood upright and let the head drop on the chest they stood out in a marked curve. His general physical condition suffered from the excessive strain. For a while he lost in weight but by November, 1912, examination showed that he was about normal so far as the respective physical functions were concerned. At home it was necessary to keep him a close prisoner for the protection of his younger brother and the community at large. The brother seemed to be perfectly normal. He is a half-brother to D. H——, the father having married the second time.

Continued difficulty in dealing with the boy at home seemed to make it advisable to renew previous efforts to have him taken care of in some institution. The crowded condition of the School for Feeble-minded prevented his admission for a time, but space for him was finally made and he was transferred to that institution. Up to the time of his admission to the institution the habit was still sufficiently strong to make it necessary to keep him practically a prisoner in his own home in order to protect his brother.

About two years after his admission to the institution the Child Welfare Commission, in going through the institution, ran across D. H——. Inquiry developed the fact that he had not had the habit since the change of Superintendents. Close watch night and day failed to catch him in the indulgence of his habit. The nurse who had him in charge immediately after his admission reported that he had the habit when he was admitted but that it had gradually disappeared.

During a recent visit to the institution on January 25, 1915, I was able to see the boy again. He is now thirteen years of age, rugged in appearance, and liked very much by the officers in the institution. The superintendent says, however, that he is not perfectly normal mentally. While he is of opinion that the boy is slightly feebleminded, yet he is so far above the average class of boys of his age in the school that it is really not the proper place for him.

As can well be imagined, criticism for castrating the boy was both severe and disconcerting, but the

severity and final outcome of the case have certainly justified the procedure. The problem presented many points for consideration which made responsibility heavy. The case is closed with a certain degree of satisfaction—certainly without regret for having treated the case as it was treated.

THE EFFECT OF INTRAVENOUS INJECTIONS OF RADIUM ON A PERSISTENT POSITIVE WASSERMANN REACTION.

By WINFIELD AYRES, M.D.,

NEW YORK.

NEARLY every physician has been at least annoyed by his inability to obtain a negative Wassermann in a certain proportion of his cases of syphilis. The writer, being no exception, wondered what effect radium would have on this condition. The histories of the following cases seem worthy of report in this connection.

CASE I.—W. Y. came under my observation in 1904. He had at that time a typical chancer and later developed secondary lesions. He was treated for four years by injections, inunctions, and internal medication and then, as there had been no evidence of disease in three years, was pronounced cured. He consulted me on January 9, 1915, because his teeth were loosening, his dentist having ascribed the condition to either medicine or syphilis. The patient had shown no signs of syphilis in ten years and had considered himself cured. His blood was taken for a Wassermann more as a matter of curiosity than because syphilis was suspected. The reaction was four plus. He was given five intravenous injections of 50 micrograms of radium at two-day intervals. On January 28 he reported that he "hadn't felt so well in years," but the Wassermann was still four plus. He was then given a 50 and at two-day intervals three injections of 100 micrograms. On February 26 his Wassermann was negative. He did not report again until May 6 when he stated he was feeling remarkably well, but the Wassermann reaction was returned four plus. He was given three injections of 100 micrograms each and on June 1 his Wassermann was again four plus. Two more injections of 25 micrograms and on June 15 the Wassermann was returned negative. Since that time he has been receiving weekly injections of 10 micrograms of radium combined with 10 milligrams of vanadium and his Wassermann has remained negative.

CASE II.—J. L. contracted syphilis in 1901 and was treated about six months with mercury pills and then received some form of intravenous injection. He was pronounced cured in 1904. He came to me in September, 1913, because he had had a Wassermann taken in June and it had been returned positive. There was no sign of syphilis, but the Wassermann was four plus. He absolutely refused to take mercury in any form and he was given neosalvarsan injections—five courses of three injections of 0.9 were given at three months intervals, but this had absolutely no effect on the Wassermann reaction. On November 27, 1914, he was given 50 micrograms of radium intravenously, but owing to an accident he was unable to report again until January 20, 1915, when he was given 50 micrograms of radium. This dose was repeated on the 22d and on the 24th. On February 10 his Wassermann reaction was four plus. Three injections of 100 micrograms each were given and on March 11 his Wassermann was negative. On May 15 his Wassermann was two plus. Three more injections of 100 micrograms were given and on June 15 the reaction was negative. Since that time he has been receiving weekly injections of 25 micrograms and his Wassermann reaction has remained negative.

CASE III.—C. W. contracted syphilis in 1908 and was treated for two years with mercury pills. He was referred to me on October 17, 1910. He showed no sign of syphilis and a Wassermann reaction was negative. I advised a second test and four months later it was returned four plus. I referred him to a physician in his own town for treatment, recommending mercury and neosalvarsan. He was treated for three years, but every test showed two or three plus. Beginning on January 27, 1915, I gave him intravenous injections of 50 micrograms of radium at two-day intervals until 250 micrograms had been injected. On February 27 his Wassermann was negative and has remained so since without further treatment, unless the local use of radium in his mouth for leucoplakia may have some influence on the reaction. This is extremely doubtful.

CASE IV.—C. L. developed a chancer which was followed by secondaries in 1902. He took mercury pills for nine months and from that time had no sign of the disease until shortly before he was brought to me in February, 1913. At that time he presented all the signs of cerebral syphilis. His Wassermann was four plus. He was given five courses of neosalvarsan (0.9), and an attempt was made to supplement this with injections of mercury, but this had to be discontinued. The patient made a complete clinical recovery, but his Wassermann reaction was one plus or stronger on every test. On March 27, 1915, his Wassermann reaction was one plus. He was given one injection of 100 micrograms of radium and this was followed by two injections of 50 micrograms each at two-day intervals. On April 12 his Wassermann reaction was four plus. He was then given a 150, 200 and a 250 micrograms injection with the result that on May 3 a negative Wassermann was returned. Since then the patient has been in perfect health, and on every occasion his Wassermann has been negative.

In conjunction with these four cases, one case of acute syphilis and one of subacute syphilis were treated by intravenous injections of radium. Neither was in the least benefited clinically in spite of the fact that enormous doses were given.

These four cases have demonstrated that radium by intravenous injection can change a persistent positive Wassermann to a negative. The first thought which comes to mind is that the change in reaction might be due to radium inhibiting the action of the reagents in a manner somewhat similar to alcohol, but a careful study of the cases proves this not to be the case. There seems to be some direct action on the disease. In Case IV the small dosage of radium had a provocative effect exactly like a small dosage of salvarsan. Yet neither case of subacute or acute syphilis was benefited by radium alone.

The next problem raised by these few experiments is whether the cause of the change in reaction was not due to radium activating antisyphilitic medicine which had been given before radium was used. But Case I had taken no medicine of any kind in seven years and it seems hardly probable that mercury could have remained in his system for that length of time.

It will require a large number of cases treated over a number of years to reach an absolute conclusion as to the benefit of producing a negative Wassermann by this method.

In these cases a solution of radium bromide was used. The dosage refers to radium element and not to the salt.

On account of the expense of treatment only private cases were treated and only those on whom I could rely absolutely to go through with the experimentation.

616 MADISON AVENUE.

Observations on Wet-Nurses.—C. Brodsky studied the effects on the mammary gland of the application of more than one child to the breasts of a single wet nurse. He found that the increased energy of sucking increased the flow of milk. In some cases the quantity of milk was doubled. In a 25-year-old primipara the largest quantity of milk given was 5,400 grams after nursing five children. The duration of lactation, provided that the proper stimulation of sucking or of the use of the breast pump is employed, is practically unlimited. Hottentots and Malays have nursed children even after becoming grandmothers.—*Archiv für Kinderheilkunde.*

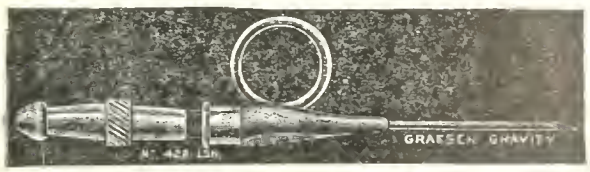
A SIMPLE PRACTICAL NEEDLE FOR INTRAVENOUS INJECTIONS.

By HERMAN R. A. GRAESER, M.D.,

NEW YORK.

ATTENDING UROLOGIST AND CHIEF OF CLINIC, GERMAN HOSPITAL AND DISPENSARY.

SINCE intravenous medication has increased considerably, and blood transfusions and saline infusions made by the gravity method, it has become necessary to devise a needle which could be held securely and passed into the veins with precision. Such a needle should be straight to allow proper cleansing and the easy passage of a wire to preserve its lumen, and short to minimize the coagulation of



Needle for use in transfusion or infusion by the gravity method.

blood within it, and give better control in entering the vein. It should be made in various sizes so that a very fine needle could be used for very small veins, and for the direct injection of small quantities of thin fluids.

This would apply to concentrated solutions of neosalvarsan, the various solutions put up in ampoules, serums, and phylacogens. The coarse needles would be used for blood and salvarsan infusions where the gravity method is employed.

In small or hard veins in old persons a 22-gauge needle may enter easily where it would be impossible to inject with an 18-gauge. The illustration herewith shows the needle and adapter made for me by Becton, Dickinson & Company, of Rutherford, N. J. It consists of a flat hub with a ring attached, which rests on the arm parallel with the vein, the opening in the needle pointing upward. If one has a steady hand this needle may be connected directly with the Luer syringe which it fits, or if preferred, a small piece of rubber tubing with a male and female adapter may be interposed. In gravity work the male hub may be connected with the tubing of the apparatus.

The needle is only two inches long, including the hub, and is made in three gauges, Nos. 18, 20, 22.

Medicolegal Notes.

Liability of Charitable Hospital for Servant's Negligence Causing Injuries to Paying Patient.—In a suit in the Alabama courts against a charitable hospital for damages alleged to have been sustained by being scalded with boiling water both internally and externally as a result of the negligence of a nurse, the defense was that having exercised due care in the selection and retention of the nurse, the defendant was exempt from all liability to the plaintiff, because of the fact that it is an institution not for profit, but for charitable purposes. "The question presented," said the court, "is one of much interest, and a subject upon which much appears to have been written in recent years. It must be conceded at the outset that the great weight of authority in this country, certainly from a numerical standpoint, lies with the defendant in this case. It appears, however, to be conceded by counsel, and we have found nothing to the contrary, that the question is an open one in this State, leaving us free to act without any constraint of the law of stare decisis, and in accordance with what we deem to be the law. . . . While it must be conceded that the great weight of authority in this country is in favor of exemption to an institution engaged in charitable work from liability for the torts of its servants or agents, yet here is some contrariety of opinion as to the principles on which this result is rested, and varied reasons are given not at all consistent the one with the other. For the purposes of this case these authorities may be grouped into three classes. One line of decisions would rest exemption from liability upon what might be termed 'the trust-fund theory,' that is, that all funds of such institutions are held in trust for the particular charitable purpose, and that it is a breach of trust to apply them to any other purpose, and that the payment of damages due to the negligence of the servants of the institution is not a purpose contemplated by the trust, and that therefore their funds cannot be diverted to the payment thereof. Other authorities rest their conclusions, it seems, upon the theory that the rule of respondeat superior does not apply to such institutions for the reason that the servants in the exercise of their duties are not engaged in the work which is for the benefit or profit of the master, and that such is essential to call for the application of this rule. Still other authorities base their conclusion upon what might be termed an 'implied-assent theory'; that is, that one who accepts the benefit of a charity must be taken impliedly to have assumed the risk of negligent injuries caused to him by servants who have been properly employed or retained in its service, or to have waived liability of a charitable institution for injuries so received."

The court rejected the first, or "trust-fund theory" because, followed to its logical conclusion, it considered that this theory would result in absolute immunity from damages of any character being recovered against such institutions, which would exempt them from liability of the servant to the patient, and to a third person, and indeed it would seem to also exempt them from damages from the breach of an expressed contract. It was also of opinion that exemption from liability could not be rested upon the theory that the rule of respondeat superior had no application.. The theory of "implied assent" was that upon which the more recent and best-considered cases seemed to the court to rest. Conceding, without deciding, that this principle was logical and well founded, it considered that it could not be given application in this case. The complaint alleged that the plaintiff agreed to pay a reasonable compensation. She depended upon no charity, she sought none, but was to pay a reasonable price for what she received. Had she been a dependent upon another's bounty, to either a great or small degree, there might have been some plausibility in the argument that it would not lie in her mouth to say that the institution should be held to strict accountability for the negligent acts of its servants, in administering the charity which she herself had sought.

The court was of the opinion that there could be no valid reason why a patient paying full price and without regard to the nature of the institution from which she received her service, dealing as she did at arm's length with the hospital, should not stand in as favorable a position as the stranger, and yet many of the cases grant relief to the latter and refuse it to the former. The court held that the principle, if held to be sound, must rest upon the fact that it is the giving and receiving of charity that creates the exemption, and not the nature of the institution administering it. The court passed by the question of liability for injury to one who in fact accepts charity in an institution of this character, as such a case was not before it. Judgment for the defendant was reversed and the cause remanded.—Tucker vs. Mobile Infirmary Assn., Alabama Supreme Court, 68 So. 4.

Implied Promise to Pay for Medical Services to Niece.—In an action for medical services it appeared that the defendant requested the plaintiff, a physician, to attend and treat the defendant's niece, who was a member of his household, her parents having been divorced. He did not inform the plaintiff that the patient was not his daughter or that he did not expect to pay for the services. The plaintiff supposed until after his second visit to the patient that she was the defendant's daughter, but then learned that she was his niece. The defendant paid a bill for drugs and one for the services of a nurse. It was held that under the circumstances the trial court was justified in finding an implied promise by the defendant to pay for the plaintiff's services.—Bigelow vs. Hill, Minnesota Supreme Court, 152 N. W., 763.

THE PREVALENCE OF SYPHILIS IN THE ARMY AND IN CIVIL LIFE.

SYPHILIS is a disease which is, perhaps, more frequent in armies than in civil life. In the army, too, it can be studied under favorable circumstances and consequently Bulletin No. 3, issued from the office of the Surgeon General of the U. S. Army, compiled by Captain E. B. Vedder, of the medical corps, should prove especially instructive and interesting. Seeing that the Wassermann reaction has been used continuously as an aid to the diagnosis of syphilis in the army since 1909 with the result that much information has been obtained with regard to both the technique and the interpretation of the reaction, it occurred to the writer that it would be instructive to apply this test for the acquisition of the information as to the prevalence of syphilis in the army. A large number of medical officers have cooperated in the performance of this task and the outcome has been a quite remarkable résumé of the subject. The subject was approached by studying groups, which may be classified as follows: (1) Those just entering the service. (2) Those who have been in the service some time. (3) Those who have recently left the service. In order to avoid fallacies inherent in the consideration of a small number of cases it was intended that each group should consist of 1,000 men. This was a convenient number large enough to avoid error, and not too large to become a matter of burdensome and useless accumulation of statistics. As a matter of fact, while 1,000 men was thus always the unit sought for, in a few cases more than a thousand men were obtained, while in other cases, for various reasons, 1,000 could not be obtained.

For the determination of the amount of syphilis in the groups studied, the Wassermann surveys have been chiefly depended on, although whenever possible these surveys have been reinforced by the clinical examination. The following conclusions were drawn from a consideration of the working of the Wassermann tests: (1) That antigens consisting of cholesterinized extracts of human heart do not give more false positives than any other antigens when used with the proper technique; (2) that the Wassermann reaction as it is performed in the army laboratory is sufficiently exact to give trustworthy results in survey work and that, therefore, the statistics presented in the bulletin may be considered reliable.

As for the prevalence of syphilis among men just entering the service, it seems fair to estimate that the percentage of the disease among the men originally presenting themselves to the recruiting officer is the same as the percentage found by the Wassermann survey on accepted recruits, plus the estimated 2.3 per cent. of rejections for syphilis. This makes a total of 19.07 per cent. of syphilis for all applicants for enlistment, or about one out of every five applicants. It may be therefore concluded that among the young men in civil life between the ages of twenty and thirty, and of the general class belonging to the occupations mentioned, the prevalence of syphilis may be estimated at at least 16.77 per cent., and there is good reason for believing that it is fully 20 per cent. The general opinion seems to be that there is a gradual and steadily increasing amount of syphilis in the army as the years of service increase, but a closer analysis of the figures demonstrates clearly that there is certainly no more syphilis among the enlisted men of the army than is to be found among recruits, and this in spite of the fact that a considerable amount of syphilis is undoubtedly contracted by these men during their period of service in the army. In fact, the investigations under discussion appear to show that so far as venereal diseases are concerned, conditions are better in the army than in civil life. A study of the tables collated, both for whites and blacks, indicates that age is the real factor governing the prevalence of syphilis and that service in the army has probably little to do with the prevalence of infections, except that to all intents and purposes they are not so numerous in the service as they would be outside.

The most important conclusions to be drawn from the work done in the army with regard to the prevalence of syphilis therein are briefly: (1) A very large number of recruits, estimated at 16.77 per cent., are already syphilitic when they enter the service. (2) Since there are only 3.44 per cent, of white enlisted men on the sick report for syphilis, it is certain that the majority of these syphilitic recruits are never diagnosed. (3) Many of these undiagnosed cases of syphilis are admitted to sick report under other diagnosis, and a certain but at present unknown amount of expense is thereby incurred by the Government. (4) From 2 to 5 per cent. of the commissioned personnel of the army are already infected with syphilis at the time they enter the service. (5) The percentage of syphilis among white enlisted men of the army, estimated at 16.08 per cent., is slightly lower than the estimated percentage of infected accepted recruits. (6) Since there are about 3 per cent. of fresh infections annually among these troops, it follows that syphilitics are leaving the service in some way faster than new cases are being acquired. (7) Study of the syphilitic registers of completed cases confirms this belief, because the rates for discharge for disability are twice as great for syphilitics as for all enlisted men. (8) Wassermann

surveys of military pensioners, insane soldiers, tuberculous soldiers, and inmates of the Soldiers' Home also confirm this belief, because they all indicate a prevalence of syphilis considerably higher than that obtaining among enlisted men. (9) Syphilis is much more common among negro troops than white troops, and is acquired at a much earlier age in the case of negroes, so that it may be expected that a very large percentage of colored men are already syphilitic at the time they enter the service. (10) The highest rate for syphilis encountered in these surveys is among the soldiers of the Porto Rico regiment of infantry. (11) About 13 per cent. of insanity in the service may be directly attributed to syphilis. (12) There is a distinct tendency in any group of men for syphilitic infections to accumulate with advancing years, so that the older the group the higher the percentage of syphilis. (13) The percentage of syphilitic infections is lower among men in the army than among similar men in civil life.

With reference to the civil population: (1) It may be estimated that about 20 per cent. of the young adult male population of the class from which the army is recruited are infected with syphilis. (2) It may be estimated that about 5 per cent. of the young men in college are syphilitic. (3) The study confirms observations that have been published already indicating that syphilis is so prevalent among negroes that it is possibly the greatest single factor in the production of disability and high mortality rates among the race. (4) The high percentage of syphilis among Porto Rican soldiers indicates that syphilis may be one of the important causes of disability among native Porto Ricans. (5) Since syphilitic infection is so common, is productive of so much disability, and has so far entirely evaded sanitary control, it is believed that syphilis is a greater menace to public health than any other single infectious disease, not even excepting tuberculosis.

The conclusions arrived at by the U. S. Army investigators are extremely valuable and give occasion for thought. It is probable, indeed more than probable, that syphilis is the greatest menace to public health, and the problem of how best to abate the scourge—for it is hopeless to imagine that it can be entirely stamped out—should be grappled with more strenuously than it has been up to the present time. No sentiments of prudishness or of false delicacy should be allowed to stand in the way of the consummation of this object.

THE URINARY AND BLOOD FERMENTS IN NEPHRITIS.

THE possible diagnostic significance of the urinary and blood ferments is a subject that has appealed to a number of investigators during the past few years. An elaborate research into the clinical value of determinations of the ferment content of the urine and blood in cases of nephritis has been undertaken by Anchise Lorenzini, who reports his results in *Il Policlinico*, Sezione Medica, August 1, 1915. He finds that amylose is present in the normal as well as pathological urine, but in a minimal quantity, demonstratable only in fresh urine and not in urine twenty-four hours old. Its disappearance is accounted for partly by the changing temperatures and partly by the action of other substances present in the urine. In the blood serum of nephritis the amylose is diminished, and this diminution is pronounced if the type of nephritis is severe. Lipase is constantly present in normal and pathological urine. In the former the content is slightly less than that of the blood. It is diminished in the urine of nephritis, and to a greater extent in the chronic than in the acute type of the disease. The lipolytic power of a given specimen of urine is, therefore, a reliable index of the degree of renal impairment. There can be no question as to the pathological significance of an albuminuria if this is associated with a diminution of the lipase content of the urine. The lipolytic power of the blood serum of nephritics is above normal, and is below normal in the agonal stage.

Pepsin may be demonstrated in a distinct quantity in the urine, with diurnal variations, being a minimum during fasting and a maximum several hours after meals. It is greatly increased if the urine contains a large number of white blood cells. It is scant in cases of chronic nephritis. The urine also contains a minute quantity of a proteolytic ferment that is active in an alkaline medium. The quantity is greater in normal than in pathological urine, and tends to vanish as the content of the urine in white blood cells tends to increase.

The reducing power of the urine varies during the day, being greater during fasting than after the ingestion of meals; it is also greater in urine twenty-four hours old than in fresh urine. In the urine of nephritics it is less than normal, and in the blood serum of these patients it is greater than in the urine. The antitryptic power of the blood serum in nephritis is greater than normal and tends to diminish as the type of the disease becomes more severe. If the urine contains a notable quantity of albumin the antitryptic power of the urine disappears.

The presence of catalase may be constantly demonstrated in the urine of acute nephritis but not constantly in that of chronic nephritis. The degree of catalytic power is nevertheless a good index of the degree of renal impairment. The blood serum contains more catalase than the urine, which fact suggests that the catalase in the urine is derived in part from that in the blood, and traverses the renal epithelium in nephritis in the same manner as does albumin.

In summing up the results of his investigations, Lorenzini states that the ferments normally present in the urine undergo a diminution in nephritis and to a greater degree in severe cases of chronic nephritis. The same ferments are present to a greater extent in the blood than in the urine, which fact would favor the hypothesis that the urinary ferments are derived, at any rate in part, from those of the blood. The proteolytic ferments alone may be regarded as derived directly from the renal epithelium.

THE "INSANITY DODGE."

THE insanity expert has become a commonplace of the comic papers through, we believe, no fault of his own, but because of the confusion between medical and legal concepts of insanity. What is the layman to think who hears three or four physicians of unimpeachable standing and impressive demeanor testify that the prisoner at the bar is insane and then hears a like number of physicians equally imposing and betitled give their opinion that he is sane? Or when several experts pronounce a criminal of unsound mind and he afterwards confesses that he was feigning? We can hardly blame the man on the street for being inclined to poke fun at the whole system of expert testimony and to refuse to be guided by anything save his own conviction in the matter. Hence has arisen the joke about the insanity dodge in murder trials which in many forms is seen in the daily press.

And yet whether or not there is such a thing as real malingering of mental disease, that is to say, the systematic and continued feigning of psychotic symptoms by a person absolutely normal mentally, is an open question. A great many physicians, especially those who have never seen a case of so-called malingering of mental symptoms, would unhesitatingly answer the above question in the affirmative. But the more a physician has to do with the criminal, the less is he apt to be dogmatic on the subject. Thus we find in a clinical study of the malingerer by Dr. Bernard Glueck in the September issue of the *International Clinics* a serious doubt raised as to whether any of these supposed malingerers are actually normal. Glueck quotes many interesting and illustrative cases gathered during his five years' study of the criminal insane and his conclusions are well worth recording.

He thinks that malingering is often coexistent with actual mental disorder so that the detection by confession or otherwise of shamming does not necessarily exclude insanity, though of perhaps an entirely different type from the feigned symptoms suggested. Malingering he says is *par excellence* the weapon of the constitutional psychopath and is the manner in which he dodges an issue. Together with pathological lying, malingering is a manifestation of the subconscious and hence when it acquires sufficient potentiality to dominate an individual's conduct for a length of time must be regarded as pathological. In conclusion Dr. Glueck warns us that the differentiation between malingering and actual mental disorder, especially when the latter is somewhat atypical in its manifestations, is often extremely difficult and we should proceed with the utmost care. Having made up our minds that we are dealing with a case of malingering, we should suspect some grave biological defect.

ETHYLHYDROCUPREIN AND THE PNEUMOCOCCUS.

IT is now four years since the introduction of ethylhydrocuprein, a derivative of hydroquinine, in the treatment of experimental pneumococcic infection. Unfortunately it, at that time, received a brief and enthusiastic attention from the newspapers which was the cause of a marked reaction when it was realized that its discoverers did not advise its use in the treatment of pneumonia in man. Since that time it has been the subject of a few bacteriological investigations, but that is about all.

The success of Cole and Dochez and Gillespie in classifying the pneumococci into four groups which could be divided serologically and which produced pneumonias of different severities, made it worth while to determine the effect of this drug upon the different strains of the organism. This is the work which Moore has done (*Jour. Exper. Med.*, 1915, xxii, 269). He found that in very high dilutions (50,000-1,000,000) the drug inhibited the growth of, and in eighteen hours, killed representatives of all four groups of pneumococci *in vitro*. There was no constant or considerable difference in the action on the four groups. Its effect upon other organisms was so much less that he suggests the possibility of its use as a test in the identification of the true pneumococcus. Quinine hydrochloride also kills the pneumococcus *in vitro*, but only in much stronger concentrations than is the case with ethylhydrocuprein. This drug also has a well marked protective action against experimental pneumococcal infection in mice in the case of type strains of all four groups of pneumococci, and this action may be efficient against as much as 1000 minimal lethal doses of the organisms. Of eighty-five mice infected with 100 minimal lethal doses or less and treated, 56, or 66.8 per cent. survived, while all the controls died. The disquieting factor in Moore's results lies in the fact that thirteen mice (15.2 per cent.) died as a result of the toxicity of the drug or from some obscure cause, the heart's blood being sterile at autopsy.

This would militate strongly against the use of this agent in the treatment of pneumonia in man, but it should prove a strong stimulus to the synthetic chemists who might be able to eliminate the toxic portion of the molecule while retaining its bacteriotropic action. Its affinity for the pneumococcus is so strong that this might be done without greatly weakening its protective action. Certainly we need some such method for the treatment of this disease. Sera and vaccines have been given rather extensive trials without striking results, and it now seems necessary to return for aid to the chemical laboratory, which, according to many possibly somewhat optimistic clinicians, has already given us some fairly efficient remedies for this so-called self-limited disease.

A RETURN TO STUDY.

DURING the past week most of the medical colleges opened and by this time the students are well into the routine of the work. While their new year is distinctly separated from the past year by a vacation, and marked in most colleges by a formal opening with eloquent addresses by leaders in medicine or prominent educators, the practising physician, though well harnessed to a daily routine, also feels the beginning of a new year and turns again to serious reading and study. The student in medical

schools has the advantage of an inspiring teacher, but the physician has the advantage of the habit of study. No physician by his efforts alone can keep abreast of the times in his profession. He, like the student in the medical college, has his helpers; he is debtor to his profession through the medical books and periodicals with their contributors and corps of workers who gather, sift, and bring to him in condensed form what it would be impossible for him to lay hold of through his own personal efforts.

To-day there is great need of study and patient, sympathetic evaluation of the facts in medicine so as not to be stampeded into casting aside a well tried for a new and acclaimed theory or to be determined to cling to an old theory in face of newly discovered facts. There should be no condemnation because facts are not understood or do not accord with some present day accepted theory nor should they be thrown aside because the theories explaining them have to be rejected. The practice of medicine never demanded more study than it does today, nor has the study ever been more interesting or more profitable.

Autopsy Finds in Army Typhoid.

The malignancy of a disease can best be understood through the post-mortem appearances, and these, as is well known, teach us the general perniciousness of mixed or superinfection which determines the complications which lead to the fatal results. At a military medical evening held recently at Metz (*Deutsche madizinische Wochenschrift*, June 3) Merkel related numerous autopsy finds in soldiers dead of typhoid. While true dysentery was found but once in association with the latter a dysenteriform condition, due, perhaps, to mixed infection, was not uncommon, and this was true also of a diphtheroid affection of the colon. The intestinal lesions were never absent and usually severe, extending even into the rectum; hence the peculiar clinical forms of colitis. The bronchial and pulmonary complications were very common and severe. There was a disseminated pneumonia, often hemorrhagic. Ulceration and necrosis of the larynx were also common. Abscesses were found in the kidneys, spleen, salivary glands, muscles, and skin. One patient injured while ill of typhoid died of tetanus. Amyloid degeneration of muscles was very common, especially in the recti abdominis. Evidence of fatal relapse was noted. The pulmonary complications appeared to cause the most deaths and cardiac failure came next. Perforative peritonitis was very rare and fatal hemorrhage was not even mentioned.

A New Treatment of Chronic Synovitis.

Having come to the conclusion that chronic joint hydrops, occurring as it does from time to time without traceable causal infection, was surgically a question of drainage, and that its persistence depended upon a loss of absorbtive power in the synovial membrane rather than upon any persistent oversecretion, F. J. Cotton (*Surg. Gyn. and Obst.*, July, 1915) conceived the idea of dealing with this condition by means of subcutaneous joint drainage. As he says, an opening into a joint is ordinarily closed in early, the epithelial layer grows over the gap, and we are where we started. In order to secure permanent drainage a gap must be made in the periphery of the capsule that cannot be covered with synovial membrane; or, as he says, a permeable scar open to the joint. Cotton's technique in securing permanent subcutaneous drainage is as follows: A long curved incision is made high up on the inner side of the knee, exposing a considerable mass of vastus internus muscle, which is split in the direction of its fibers. Beneath this lies a firm layer of fibrous capsule; still farther beneath, and well differentiated, lies the synovial lining—thin, pale and abnormally tough in consistency. An incision is made through the fibrous capsule and synovial membrane and the contained fluid is allowed to escape. The edges of the synovial membrane are then pulled well out through the gap in the fibrous capsule, rolled back over the edges of this capsule and sutured with catgut to its outer surface, so as to leave no exposed edge of synovial membrane. The joint is then washed out with saline solution and left half full. The vastus internus is brought together over the gap in the synovial membrane by lightly drawn catgut mattress sutures, the skin is sutured, dressings are applied, and the knee is bandaged down on to a straight ham splint. This scheme worked out successfully in the three cases in which Cotton has had an opportunity to test it; and we should say, with him, that the operation is worthy of further trial.

News of the Week.

Shortage in the American Ambulance Service in France.—Efforts to enlist young men in the service of the American Ambulance in France are being made in this country, owing to the fact that the reopening of American colleges and universities has caused many volunteer workers to return, and this at the very time when all the ambulances and hospitals are overworked by reason of the great number of wounded resulting from the increased activity at the front.

German Hospitals in Belgium.—According to the *Telegraaf* of Amsterdam the Germans are preparing to establish great hospitals for their wounded in Belgium. Municipal and other buildings at Louvain and other places have been inspected recently by German physicians and officers to see if they could be made into hospitals, and equipment for them has been ordered from Germany.

Dr. Hermann Fischer of this city, who headed a party of surgeons and nurses sailing from New York on September 9, was detained at Kirkwall by the British authorities because he had neglected to take his naturalization papers to show that he was no longer a German. The necessary papers having been received, however, he was released the end of September and has reached Copenhagen.

Serbia Honors Americans.—It is reported from Nish that Crown Prince Alexander has decorated forty-three American physicians and sanitary engineers, in recognition of their services in stopping the epidemics which broke out in Serbia after the war began. The Americans decorated were those sent out by the American Red Cross and the Rockefeller Foundation.

More Cholera in Galicia.—A despatch from Amsterdam says cholera still is raging in Galicia, and according to the home office 300 cases have been reported.

Health of the Canal Zone.—The report of Dr.

Charles F. Mason, chief health officer of the Canal Zone for July, states that the number of deaths among the employees for the month was 17, of which 10 were from disease, giving a rate of 3.34 per 1,000, as compared with 3.61 for June and 4.12 for July, 1914. Among the civil population of the Zone, numbering 30,057, there was a total of 37 deaths; of these, 29 deaths were from disease, giving a rate of 11.58 per thousand, as compared with 13.15 for the preceding month, and 14.64 for the corresponding month of last year.

Death Rate in New York.—During the week ended September 25 there were in this city 1,236 deaths, giving a rate of 11.11 per 1,000 persons, as against 1,323 deaths and a rate of 12.36 for the similar week last year. The death rate for the first thirty-nine weeks of 1915 was 13.43, as compared with a rate of 13.90 for the corresponding period of last year.

Death Rate in Chicago.—During the week ended September 25 there were 487 deaths in Chicago, giving a rate of 10.4, as compared with 660 deaths and a rate of 14.1 for the preceding week, and 569 deaths and a rate of 12.4 for the corresponding week in 1914.

Beriberi in Labrador.—Dr. Joseph A. Andrews, stationed at Indian Harbor, Labrador, for the Grenfell Mission, who returned recently, is reported to have found the natives of that place suffering from beriberi as a consequence of living chiefly on white bread. When they substituted brown or black bread the epidemic ceased.

Foot-and-Mouth Disease in Illinois.—The United States Agricultural Department has quarantined three counties in Illinois against the foot-and-mouth disease. This action was taken owing to the discovery of the disease in two herds in La Salle County. One of these herds, containing sixty-five cattle, was found on a community pasture and the fact that the herd belonged to twelve different owners led the authorities to quarantine the adjoining counties with a view to checking its further spread.

Dr. Heiser Mentioned for Health Commissioner.—It is reported that Dr. Victor G. Heiser of the U. S. Public Health Service, formerly director of health in the Philippines, has been invited to become health commissioner of New York City to succeed Dr. Goldwater, who has resigned and is only waiting until his successor is appointed. The success of Dr. Heiser in stamping out the plague, cholera, smallpox, and beriberi in the Philippines was phenomenal and has placed him in the front rank of the world's sanitarians.

Medical Department of Columbia University.—The opening exercises of the College of Physicians and Surgeons of this city, the medical department of Columbia University, were held on September 29. The address of welcome was delivered by President Butler and this was followed by the opening address by Dr. Francis Carter Wood, director of the Crocker Cancer Research Fund.

The Long Island College Hospital opened its fifty-seventh session in the auditorium of the Polhemus Clinic September 28 with an address by Dr. Horace D. Arnold, dean of the Graduate School of Medicine in Harvard University.

Harvey Society Lectures.—The first lecture of the eleventh course of the Harvey Society will be delivered at the Academy of Medicine, New York, on October 16, at 8.30. The lecture, entitled "Recent Studies on School Children, with Special Reference to Hookworm Disease and Sanitation," will be delivered by Prof. C. W. Stiles of the Hygienic Laboratory, Washington.

Conference of Charities and Corrections.—The first annual Westchester County (N. Y.) Conference of Charities and Corrections will be held October 21 in Yonkers. Among the objects of the conference are: To afford workers an opportunity to hear their problems discussed by experts, to exchange opinions and experiences about activities along their various lines, to secure better co-operation between agencies, and to inform the public about the numerous welfare activities carried on throughout the county. It is expected that a permanent organization will be effected and that a similar conference will be held each year henceforth.

The Volunteer Hospital.—The directors of the Volunteer Hospital in New York City have begun a campaign to raise enough money to complete the new building at Beekman and Water streets in accordance with the plans which were made when the old hospital was abandoned. At that time it was decided that a seven-story structure should be built, but sufficient funds were lacking, and only three stories were erected. The hospital takes all emergency cases on the lower East Side from Catharine street to the Battery and from Broadway and Park Row to the East River.

Dr. Allan McLane Hamilton has returned from Europe and has resumed practice at 43 East Twenty-fifth street, New York.

Dr. Richard P. Strong, who directed the anti-typhus campaign of the American Red Cross Sanitary Commission in Serbia, has returned. Shortly before leaving Serbia Dr. Strong was decorated with the order of San Sava.

Dr. Mary M. Crawford of Brooklyn, who has been connected with the American Ambulance Hospital at Neuilly, Paris, for a year, returned recently.

Dr. Wilbur A. Sawyer, director of the State Hygienic Laboratory and lecturer in hygiene and preventive medicine in the University of California, has been appointed a member of the California State Board of Health and secretary of the board.

Dr. William C. Hollopeter has resigned from the chair of pediatrics in the Medico-Chirurgical College of Philadelphia, after an occupancy of fifteen years. He had formerly held the Chair of Clinical Professor of Pediatrics from 1892.

Dr. James Craig Neal has been appointed instructor in obstetrics and gynecology in the medical department of the University of California.

Dr. Alexander Spingarn has been appointed assistant pediatrist at the Methodist Episcopal Hospital, Brooklyn, N. Y.

Dr. D. A. Carmichael of the United States Public Health Service, recently in charge of the Marine Hospital at Vineyard Haven, will be retired at the end of November, having reached the age limit. Dr. Carmichael has been in the service for nearly thirty-five years.

Dr. Thomas B. Shea has been appointed chief of the medical division of the Department of Health of Boston.

Dr. R. G. Pearce has been made assistant professor of physiology in the medical department of the University of Illinois.

Dr. H. Mullany has been appointed deputy health commissioner of Boston.

Dr. Bernard W. Carey has been elected city physician of Fitchburg, Mass.

Dr. George W. Beatty has been appointed assistant pediatrist at the Methodist Episcopal Hospital, Brooklyn, N. Y.

Dr. Eugene M. McCampbell has been appointed professor of preventive medicine and head of the newly created department of public health at the Ohio State University, Columbus.

Removals.—Dr. R. J. E. SCOTT has removed to 307 W. 79th street.

Dr. PAUL E. BECHET has removed to 531 Madison avenue.

Bust of Dr. Weir Mitchell.—A bronze bust of the late Dr. S. Weir Mitchell has been presented by Mr. and Mrs. Walter D. Ladd to the Jesup Memorial Library in Bar Harbor.

The Clinical Congress of Surgeons of North America will meet in Boston on October 25-28. As usual the days will be devoted to clinics, the evenings to the reading and discussion of papers. The president of the Congress is Dr. John B. Murphy, the president-elect Dr. Charles H. Mayo, and the secretary Dr. Franklin H. Martin of Chicago.

Medical Society Elections.—THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION, at its meeting in Atlantic City on September 14-16, elected the following officers: *President*, Dr. Jefferson A. Gibson, Denver; *Vice-Presidents*, Drs. J. Willard Travell, New York, Frank B. Granger, Boston, William L. Clark, Philadelphia, Sidney A. Twinch, Newark, N. J., and William Martin, Atlantic City; *Treasurer*, Dr. Emil Henck, New York; *Secretary*, Dr. Byron Sprague Price, New York; *Registrar*, Dr. Frederick M. Law, New York.

THE SOUTHWEST TEXAS DISTRICT MEDICAL SOCIETY held its annual meeting at Corpus Christi on September 14 and 15, electing the following officers: *President*, Dr. E. H. Lauvignet of Laredo; *Vice-President*, Dr. C. P. Yeager of Corpus Christi; *Secretary-Treasurer*, Dr. L. J. Manhoff of Aransas Pass.

THE WASHINGTON COUNTY (VT.) MEDICAL ASSOCIATION, at its annual meeting at Barre on September 14, elected the following officers: *President*, Dr. J. P. Gifford of Randolph; *Vice-President*, Dr. G. S. Bidwell of Waterbury; *Secretary-Treasurer*, Dr. C. H. Burr of Montpelier.

THE KENTUCKY STATE MEDICAL ASSOCIATION, at its annual meeting in Louisville, September 21-23, elected the following officers: *President*, Dr. Ap Morgan Vance, Louisville; *Vice-Presidents*, Dr. M. F. Hoag of Quicksand, Amos Davis of Eastington, and J. B. Mason of London; *Secretary*, Dr. A. T. McCormack of Bowling Green; *Delegates to the American Medical Association*, Drs. W. W. Richmond of Trenton and Carl Louis Wheeler of Lexington.

THE FAIRFAX COUNTY (VA.) MEDICAL SOCIETY, at its annual meeting in August, elected the following officers: *President*, Dr. Llewellyn Powell, Alexandria; *Vice-Presidents*, Drs. T. F. Dodd, Theological Seminary, and D. C. Cline, Dumfries; *Recording Secretary*, Dr. T. C. Quick, Falls Church; *Corresponding Secretary*, Dr. W. P. Caton, Accotink; *Treasurer*, Dr. E. L. Detwiler, Herndon.

Obituary Notes.—Dr. KENNETH FRANK JUNOR of Brooklyn, N. Y., a graduate of the New York University Medical College in 1886, a clergyman and lecturer of note, and a member of the American Medical Association, the New York State and Kings County Medical Societies, and the New York Academy of Sciences, and formerly a missionary in China and in the Island of Formosa, died in Toronto, Canada, on September 26, aged 69 years.

Dr. BENJAMIN S. LUCAS, formerly of Hartsville, S. C., died at Walhalla on September 5 at the age of 82 years. He was a graduate of the Charleston Medical College in 1856 and began practice in Keshaw County. He served in the Confederate army during the Civil War and at its close began practice again in Hartsdale. He retired about two years ago.

Dr. ANDRES VICTOR JOVA of Newburgh, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1883, a member of the American Medical Association, the New York State and Orange County Medical Societies, and the Newburgh Medical Society, and visiting physician to St. Luke's Hospital, Newburgh, died at his home on September 20, aged 54 years.

Dr. ARCHIBALD FOWLER ALEXANDER of Paterson, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1895, a member of the American Medical Association, the Medical Society of New Jersey, and the Passaic County Medical Society, physician to the General Hospital Dispensary, Paterson, for three terms a member of the Board of Education of Paterson, and a former Police and Fire Commissioner of that city, died at his home on September 23, aged 42 years.

Dr. PHILANDER F. WELLMAN, formerly of Coffeyville, Kan., and a pioneer physician of that State, died at the home of his son in Kansas City, on September 16, aged 77 years.

Dr. ALPHONSE JOSEPH PIERRE GARNEAU of Fall River, Mass., a graduate of Laval University, Medical Department, Quebec, in 1893, and a member of the Fall River Medical Society, died at his home from heart disease, on September 10, aged 48 years.

Dr. CHESTER E. COULTER of Ogden, Utah, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1883, died recently at his home, aged 60 years.

Dr. FREDERICK D. BICKFORD of Salt Lake City, Utah, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1882, died at Fillmore, Utah, on September 9, after a long illness, aged 54 years.

Dr. JOHN LESTER SIVERT died at Waynesburg, Pa., on September 12, at the age of 33 years. He was graduated from the University of Nashville, Tenn., in the class of 1909. He formerly resided at Nuss, W. Va.

Dr. JOHN W. WADE died at Millville, N. J., on September 14 at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1884. He was president of the Millville Board of Health and of the Cumberland County Mosquito Extermination Commission. He was a member of the Cumberland County Medical Society, and of the New Jersey State Medical Society, and a Fellow of the American Medical Association.

Dr. FREDERICK FILLMORE BURTIS of New York, a graduate of the Albany Medical College in 1898, a member of the Schenectady Medical Association, and surgeon on the SS. *Advance* of the Panama Railroad and Steamship Company, died on board his vessel on September 6, aged 38 years.

Dr. AMELIA E. BURROUGHS of Boston, Mass., a graduate of Cleveland University of Medicine and Surgery, Cleveland, O., in 1881, and a member of the American Institute of Homeopathy and the Massachusetts Homeopathic Medical Society, died at her home on September 25.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MILITARY HOSPITALS—FROST-BITE AND MINOR EFFECTS OF COLD—SALE OF OPIUM—OBITUARY.

London, Sept. 17, 1915.

THE administration of our military hospitals has lately adopted some enterprising if rather unexpected methods, one of them being women's work with the object of releasing men for the front. The Royal Victoria Asylum for the orphans of soldiers and sailors has been transformed into a completely equipped institution for the reception of 1,500 military patients under Lt.-Col. Bruce Porter, as commandant. About 180 acres of open ground was placed at his disposal and he has established an extensive system of hut-wards, each forming a separate home for twenty patients in charge of a sister. The dining hall has been furnished as an art gallery and the meals are taken in the several homes. The commandant, considering that many of the inmates will seek an open-air life after the war, aims at making the hospital an Imperial recruiting ground; he has not laid down a strict set of rules, but trusted the men and found their behavior exemplary. Women's work has also been introduced in various departments, and the reports of their ability, self-sacrifice and skill, although untrained in nursing, show that they have given most useful aid in attending to various requirements of patients, both by day and night, and diminishing the number of orderlies needed.

Princess Christian on Saturday opened and handed over to the War Office a new military hospital on the outskirts of Windsor Park, with accommodations for 120 patients. The British Red Cross contributed £10,000 and the further sum necessary was collected by the Princess herself. The construction of the building is on the lines of the Red Cross Hospital at Netley. The floor of each ward projects eight feet beyond the outside wall so that through doors the beds can be wheeled out and left for a time in the air under cover of canvas. Sir Wm. Taylor, late Director-General, Army Medical Service, is the commandant, and Major Buckley, assistant. Gas radiators and slow combustion stoves are used for heating and the light is provided by electricity. There are six pavilions with twenty beds each for patients arranged in a semicircle facing the south. The nurses and resident staff are accommodated in the other general buildings, which contain also an up-to-date operating theater, dispensary, mess-rooms, stores, sitting-rooms, etc., for medical officers, kitchen and everything necessary for a complete hospital.

Another hospital has been acquired and extended by the London County Council and handed over to the War Office as a hospital in connection with the Avery Hill Training College. It will accommodate 250 or more wounded, and a considerable number are already under treatment. Spacious grounds adjoin the open space of the college, and the institution is staffed by members of the Greenwich and Woolwich division of the Red Cross societies working in shifts. The beds have been mostly manned by those endowing them in honor of heroes of the war.

During the last winter many soldiers in the trenches suffered from the effects of the cold on their feet—not exactly frost-bite, but a lesser effect spoken of as "trench frost-bite," a condition known in previous campaigns. Necrosis is very rare in the milder affection, thought common in the severe. A number of cases received into the military hospitals in Edinburgh from the war field have been under Profs. Lorain Smith and James Ritchie, together with Dr. James Dawson of the Royal College of Physicians' Laboratory. They have further recorded some experiments on rabbits' feet subjected to intense cold. Their investigation was promoted by the Medical Research Committee, and their experiments show, as those of previous observers do, that the slighter stages of true frost-bite are essentially the same as those of the milder disease. In this an exudative inflammation attacks the parts directly exposed to the cold, the effect of which is more intense when combined with moisture, *e.g.* if due to wet earth as compared with dry. The swelling of the feet of rabbits subsided much more rapidly than that of men. The condition is one of damage to tissues, from which recovery can only occur after a prolonged process of regeneration. Consequently the main effort of the medical man must be directed toward prevention. The considerations for prevention offered by these investigators are that soldiers should massage their feet before going into the trenches, there being some evidence that this has succeeded to a considerable extent. To shorten the time in the trenches would be the best preventive, since as a rule the symptoms begin after forty-eight hours' exposure. Men who have been exposed without being attacked should persistently massage their feet when resting between their turns in the trenches. Constriction of blood vessels should be avoided; boots, leggings, socks, puttees are specially to be considered in this respect. Maintenance of good circulation in the feet is important—clothing of legs and thighs is concerned as to this. Slight swelling after a turn in the trench should have attention before taking another turn. Rest is of the first importance when disablement is threatened. On the march, as soon as billets are reached measures should be taken for resting the feet as much as possible. But it is better not to warm them in any way that may cause congestion, the return to normal circulation should be delayed rather than hurried.

At the late meeting of committee of the General Medical Council the question of the sale of laudanum was considered in view of a correspondence that has recently taken place between the city coroner, the pharmaceutical society and the Lord President of the Privy Council. The last-named questioned whether the society's policy, as stated by its Law Committee, is to be defended. That policy is that when "laudanum" is asked for the 1914 preparation should be served and the poison-book signed, but when the 1898 preparation is demanded great care should be taken to label it as such, the purchaser's attention being called to the fact. In one way it looks as if the recommendation were designed to facilitate the sale to the public of this dangerous drug instead of restricting it. That there is a large sale is certain—so large that no authority less than Parliament could put an end to it, and there is no prospect of any such action. Since the B. P. raised the strength of *Tinct. opii* we have had two preparations passing under the English synonym—a constant danger to which attention is every now and then directed afresh. The official drug was increased in strength by the last B. P. in order to make it the same as that of the

international agreement, which was entered into for the safety of the public in all countries. As it seems impossible to prevent the public obtaining opiates in various forms, it is certainly an advantage for any preparation known by the same name in different countries to be of the same strength in all.

Dr. T. Glover Lyon, many years physician to the City of London Hospital for Diseases of the Chest, died on Aug. 31, at the age of 60. He was a Cambridge Wrangler and the originator of the Glover-Lyon system of ventilation, a subject on which he took the greatest interest. He contributed to societies and journals on various subjects connected with hygiene.

Dr. F. W. Saunders, who died at Hythe, aged 52, a Cambridge graduate, had been medical superintendent of Luxor Hospital and author of "Stepping Stones to Health on the Nile."

8. Study of a Case of Epidemic Typhus Fever Imported Into Central New York. I. H. Levy and J. L. Kantor.
9. Blood Pressure. C. Phipps.

2. Acute Perforation of Ulcers of Stomach and Duodenum.—I. J. Walker states that the history of disturbance of the stomach or duodenum should always be sought for in cases of suspected perforation. Sudden, severe epigastric pain is the most constant symptom in the diagnosis of this condition. Shock is an inconstant symptom. The value of the absence of liver dulness as a sign of perforation of the stomach or duodenum has probably been overestimated. Simple closure of the perforation, with drainage of the peritoneal cavity is the safest procedure in the majority of cases. The mortality can be diminished by greater care in the diagnosis and in the treatment of chronic lesions referable to the stomach and duodenum, so that but few are allowed to reach the stage of perforation, and even these should be given the benefit of surgical measures while the chances of recovery from operation are still good.

3. Traumatic Rupture of Duodenum.—D. Cheever points out that local pain, muscle spasm, tenderness, increasing pulse rate, later vomiting, perhaps shifting dulness in the flanks, and leucocytosis unless the toxemia be overwhelming, constitute the familiar picture of a severe abdominal lesion. A word of warning is uttered, however. If the rupture be retroperitoneal, the condition may at first be masked, but soon a tender tumor, not shifting, in the right hypochondrium and umbilical region, with evidence of physical shock, will give the clue. If intraperitoneal, the effusion may cause pain not so marked at the point of rupture as in the more dependent portions of the abdomen,—the iliac fossæ or the pelvis, due apparently to the intense irritation of the peritoneum by the gravitated contents. In the author's case this was the cause of an ill-placed primary incision and loss of time. Absence of liver dulness, a sign handed down from text-book to text-book as pathognomonic of rupture of a hollow viscus, is in reality a hollow mockery. It is very rarely demonstrable in the early and curable stages of a perforative peritonitis, and when it is found it simply gives assurance of the correctness of the diagnosis and of the hopelessness of intervention.

5. Acute Pancreatitis.—C. E. Durant alludes to the urgency of this condition, particularly in relation to the rapidity with which necrosis occurs in some cases, and to the overwhelming toxemia as a factor of great importance in the same connection. Even in instances in which the onset is less severe and in which more or less localized suppuration follows, such serious and probably fatal complications as subphrenic abscess, extensive suppuration in the peripancreatic fat, or general peritonitis may be looked for. The danger of hemorrhage in cases of persistent sinus is not to be forgotten. The author emphasizes the great importance of early diagnosis and prompt operation in acute pancreatitis.

7. Genetic Factors and Age of Onset in Hereditary Epilepsy.—D. A. Thom concludes from his investigations as follows: Named in the order of their potency in the production of an early onset of the epilepsy in the offspring, feeblemindedness came first, followed by migraine, epilepsy, alcohol, and insanity. With the exception of alcoholism all the maternal defective factors were manifested in the offspring at an earlier date in the form of epilepsy than those factors transmitted by the father. When both parents had the same defect the onset was at an earlier date than in those cases in which only one parent was defective. There was practically no difference between the average age at onset in those cases inheriting two or three defects and in those cases in which the family history revealed but one. Those cases with direct heredity averaged an earlier onset than those cases with collateral heredity. The average age at onset in one hundred and fifty-seven cases with heredity was a little over eight years younger than two hundred and five cases computed without reference to heredity. Thirty-nine per cent. of the entire group had more than one hereditary defect in the family history. Eighty per cent. of the cases had direct heredity, and fifty-eight per cent. of the entire group gave a history of epilepsy in some member of the family. Eleven cases, the offspring of epileptic parents and the parents of an epileptic offspring were free from mental defects themselves.

9. Blood Pressure.—C. Phipps finds a difference of 5 or 10 mm. in the blood-pressure reading may be observed, depending on whether the pressure be determined by palpation or auscultation, but neither method can be said to be the more accurate. The blood-pressure reading may vary in the same individual between the right and the left arms, thighs, or calves, or between arm and thigh and calf; this variation is in no way uniform. The variations are apparently as great in young individuals as in old, and in cases showing healthy arterial walls as in cases in which there is arteriosclerosis. The location of the artery, especially in its relation to other structures such as bone and muscle, is probably of much greater importance in determining the blood-pressure reading than is thickness of the overlying tissues. A difference between the right and left brachial pressures is by no means diagnostic of aortic aneurysm. The presence of a higher pressure in the leg than in the arm is not diagnostic of aortic insufficiency, although this has been stated by previous observers. Blood-pressure in the vessels of the leg and that in the vessels of the arm are by no means "practically the same."

1. Cardiovascular Toxins.—R. N. Willson describes the lesions recognized in the hearts of patients dying during the course of or from the acute infectious diseases. Each represents a type. Cloudy swelling; edema; vacuolization of the nuclei and cells; atrophy of the fibers; pigmentary, fibroid, and fatty degeneration; and fragmentation, are the important muscle lesions, common at some time to all. Typhoid fever presents Zenker's hyaline degeneration of the fibers. The cardiac nerve lesions, noticed so little and their significance even less clearly understood (as in influenza, diphtheria, etc.), may all be comprehended in the different phases of fatty degeneration. The nerve changes begin usually in the myelin sheath, and the axis cylinder often takes on a swollen and beaded appearance. The degenerative lesions in the cardiac ganglia have not, as yet, been thoroughly studied. The point given special emphasis is the fact that in every case of infectious disease all the cardiac structures are injured. Some require time and rest for their rehabilitation. The greater portion of the cardiac damage can never be repaired.

3. Muscular Relaxation in Treatment of High Blood Pressure.—M. Grossman describes a system of relaxation exercises which he finds of considerable value in the treatment of high blood pressure. He finds that one does not by relaxation remove the primary causes, such as nephritis, arteriosclerosis, etc., but one does markedly influence the mental state accompanying these conditions, thereby reducing the increased tension in the blood vessels due to this factor, and also minimizing the dangers which accompany this state. In employing this method of maintaining blood pressure at a lower level, there is provided not only a constant safeguard but also a greater control of the blood-pressure regulating mechanism. The results obtained in the cases of high blood pressure treated by muscular relaxation are said to be better and more permanent than those obtained by medicinal or any other measures.

6. Ether Administration.—W. O. Weiskotten in detailing the advantages of this type of anesthesia states that ether inhalation should be used unless contraindicated or unless the administrator has had sufficient experience with the other methods of administration. The open drop method is in common use and is preferable to the closed douche method. Artificially warmed vapor with a suitable inhaler is preferable to cold vapor for all inhalation anesthesias. Nasal, pharyngeal, or endotracheal insufflation of warmed ether vapor possesses great advantages and should be used when specially indicated. Rectal etherization when indicated is comparatively simple and a safe method when the proper technique is employed.

8. Erythremia.—R. R. Mellon reports a case which he regards as typically one of erythremia, and clinically as the well known cardio-vascular nephritic complex, plus the polycythemia and mild splenomegaly. Benzol in the usual doses given did not produce any change in the patient's condition. Although the number of red cells has been reduced to normal in some instances through the use of this agent, such a procedure appears to the author as of questionable value for two reasons: first, because of the sudden deaths occurring in cases of leucemia in which apparently only good had resulted from the drug's use; and, second, according to the findings of von Jaksch, because its administration would seem to be illogical. If, as he shows, the corpuscles are of lessened physiological worth, then the increase in number would seem to be compensatory. A destruction of this excess would then react only in a deleterious manner. Since the few symptoms that the author's patient complained of were readily alleviated by nitroglycerin, the author did not think it justifiable to resort to drastic measures merely to reduce the number of red cells.

9. Blood Urea in Renal Conditions.—A. J. Underhill concludes from his investigations that the retention of urea is positive evidence of kidney incapacity. The functional capacity of a large proportion of the kidney substance may be impaired without the retention of blood urea. As long as what remains of the kidney tissue is sufficient for the physiological needs of the body, under normal conditions retention does not result. Retention is evidence of overwork on the part of the remaining functioning kidney cells. In many instances the diet can be so regulated that the impaired kidney cells work well within their capacity. The destruction of tissue protein with an impaired kidney capacity may lead to urea retention, as much so as the ingestion of too much nitrogenous food. Diuretics and an active eliminative treatment are contraindicated when there is retention. The estimation of the urea content of the blood is the most practical method of following the course of a patient with impaired kidneys. It is more useful than the color or other tests in that it is an index of the actual condition of the patient. It can be used as a guide in the treatment of patients with impaired kidney capacity in preparation for operation. A blood urea above 0.6 gram to the liter is an indication for caution before operation when this is contemplated. A blood urea above one gram to the liter contraindicates operation.

2. Relation Between Gastric Ulcer and Cancer.—By A. J. Ochsner. (See MEDICAL RECORD, June 26, 1915, page 1092.)

3. Decomposition Food Products as Cardiovascular

Poisons.—R. N. Willson points out that these toxic substances act in one or all of three ways: (1) through a chemical toxemia and a direct poisoning of the body tissues; (2) through a bacteriemia, as in the frequent colon bacillus infections, and (3) by the formation of poisonous gases, which not only are in some measure absorbed, but also, by mechanically displacing and discommoding, embarrass organs above and below the diaphragm through gastrointestinal distention. In all three of these forms of food influence, the first recognizable effect is on the cardiovascular system. The author has experimented on laboratory animals and on himself, and has questioned very carefully patients in his care with a view to gaining light on this point. From all three sources he states that he has obtained ample evidence that the heart and vasomotor system experience very early the influences of a food toxemia of whatever nature. Usually there is a marked quickening of the cardiac action, often a distinct palpitation; almost always in the acute stages (before collapse) there is a marked elevation of both the systolic and diastolic pressures. Later, as the heart begins to tire, the systolic pressure may fall and the rhythm become irregular. Not infrequently the author has seen distinct signs of cardiac dilatation in the entire absence of abdominal distention. It would seem, therefore, as though the clinical symptoms suggesting a toxemia, especially as reflected in the cardiovascular system, are to be ascribed in the main to poisons elaborated in the intestine, but not from any one group of foodstuffs. The only requisite would seem to be that a given food substance or one of its constituents or end-products shall prove toxic for its individual host. The summer heat of the bowel, the retention decomposition of masses of undigested and often indigestible food, the presence even of food substances that are innocuous and tissue builders in other individuals, only provided they are toxic for the given one—provide all the conditions favorable to the production of acute cardiovascular crises, which, if repeated often and persistently enough, will result in cardiovascular disease.

5. **Casualties of Modern Naval Warfare.**—By F. E. McCullough. (See MEDICAL RECORD, July 3, 1915, page 41.)

8. **Management of Peritonitis.**—W. D. Haggard states that the most essential treatment of this condition, with or without operation, is an absolute prohibition of anything whatsoever by mouth, with immediate preparation for operative relief when possible. When for any reason this cannot be done the continuance of this principle with the addition of deep morphinization is the most dependable method. After operation drainage by the glass tube suprapubically and the employment of the upright posture and proctoclysis are well-nigh routine.

9. **Post-Mortem Reflexes.**—J. H. Catton concludes from his observations that the tendon and superficial reflexes disappear at death. Muscular irritability to mechanical stimulation is increased immediately following death, and continues to increase to a maximum and then to decrease, disappearing at about sixty minutes post-mortem. Since a similar increase in muscular irritability is observed in certain organic diseases of the nervous system, these reflex studies and similar studies of the electrical reactions of muscle and nerve following death should lead to new aids in the diagnosis of nervous disease. In eliciting tendon reflexes, one must be careful to tap only muscle-free tendon. The instrument must be made to stroke and not dig into the sole in eliciting the plantar reflex. The persistence post-mortem of many reflexes about the wrist cautions one not to confuse them with the periosteal reflexes in life.

10. **Elimination of Potassium Iodide in the Urine.**—W. A. Wovschin notes that the major portion of the eliminated potassium iodide is excreted in the first twenty-four hours, from 5 to 10 per cent. is given off in the second twenty-four hours, and by the third day only a trace of or no potassium iodide is excreted. As is to be expected, the amount of potassium iodide recovered never equals or even approximates the amount introduced, indicating that other avenues of elimination (skin, saliva, etc.) excrete a considerable portion, and perhaps part may be utilized in thyroid-protein moleculization. Patients who expectorate a great deal excrete less potassium iodide in the urine. The total elimination of potassium iodide in nephritic cases, as compared with other diseases, is the lowest and serves as a hint of poor renal function. When the potassium iodide is given per rectum in the nephritic cases there is a more notable elimination, due probably to slower absorption and the proctoclysis acting as a renal stimulus.

11. **Quinine and Urea Injections in Hyperthyroidism.**—L. F. Watson presents the results of a study of the quinine and urea treatment in fifty cases of goiter in which it was used. The method is recommended only for the control of the symptoms of hyperthyroidism in cases of toxic goiter, and is not recommended for the removal of the tumor in atoxic (simple) goiter for cosmetic reasons alone. The injection does not relieve the symptoms of advanced toxic goiter when the vascular and nervous systems have been permanently damaged. Much depends on a proper selection of cases; the necessity of preventing pain from any injection, by the use of local anesthesia, is of vital importance; if acute attacks of hyperthyroidism are to be prevented, the use of preliminary injections into the most prominent portion of the goiter, of a few minims of sterile salt solution given at one to three day intervals, followed by injections of sterile water, are found indispensable; the result of the quinine and urea injection depends on the amount of tissue destroyed. The quinine and urea injection in experienced hands is a harmless procedure; it is almost painless, and there is no post-injection discomfort. It is suitable for use only in a hospital by men skilled in goiter work. The gradual improvement of the exophthalmos in certain patients following the quinine and urea treatment points to a control exerted by the thyroid on the exophthalmos, through the sympathetic nervous system, as first suggested by Landström. The author believes the greatest field of usefulness for the injection is to be found in those cases of beginning hyperthyroidism not severe enough to justify operative treatment, and as a preparatory measure to partial thyroidectomy in chronic cases of toxic goiter in which the patient is too ill to warrant any form of immediate operative procedure.

14. **Treatment of Syphilis of the Brain.**—G. O'N. Ireland and C. S. Wilson find that the injections of 1 50 grain of mercuric chloride intradurally, by the method of Byrnes, is apparently safe. Autogenous serum is much preferable to pooled serum. The reactions are a little more severe than those following the Swift and Ellis method in which 40 per cent. salvarsanized serum is used. A clinical improvement usually appears after about five treatments; 75 per cent. of the authors' cases showed this improvement. A tendency to relapse to their former condition was observed in about 40 per cent. of those at first improved. The clinical improvement is more marked and rapid than the serological. How permanent the improvement will be the authors are unable to state, as the time of observation is too short. The colloidal gold test is the most resistant to change. It is possible to have clinical general paralysis with a negative Wassermann reaction in blood serum and spinal

fluid, but in the above series the colloidal gold test was uniformly positive.

7. The Strength of Picric Acid as an Antiseptic. H. L. Tidy.

2. Trench Frostbite.—J. L. Smith, J. Ritchie and J. Dawson summarize their conclusions as follows: The soldiers should practise massage on their feet before going to the trenches. A study of the cases shows that the symptoms begin to be felt, as a rule, after 48 hours' exposure. It is clear, therefore, that to shorten the time in the trenches would be the most essential measure of prevention. While men who have been exposed to the conditions causing frostbite without having been affected are resting between their turns of trench duty, they should persistently practice massage of their feet twice daily. Careful attention should be given to anything which may constrict the blood vessels. Constriction by boots and puttees should be avoided. Loose moleskin leggings would probably be found more suitable than puttees, as they would provide warmth without constriction. The advantage of leggings is that they provide the protection of an ample cushion of air and they drain more readily than compact wrappings, the existence of a non-conducting air cushion being thus reestablished. The soldiers wear boots of a large size, but they have a practice of putting on two pairs of stocks, and this probably tends to a certain amount of constriction. It was observed that the excoriations were situated on the outer and inner borders of the feet, and this fact suggests that some degree of constriction existed. It is significant that the parts most liable to trench frost-bite are the parts where under ordinary circumstances callosities and corns are most frequent. The question arises whether the upper leather of the boots could be made more pliable without diminishing the stability of the sole or of the boot generally. The soldiers very commonly cover their feet with oil and derive benefit from this. There may be several advantages in this. Among other effects it will act as a bad conductor of heat; it may minimize the effect of the wet; it may keep the leather of the boots more pliable and its application may be the occasion of a thorough massaging of the feet. In order to obtain the full effect the oil should be of high boiling-point and be used in considerable quantity; semi-solid oils such as vaseline would probably give the best results. To maintain the circulation in the feet it would be helpful to increase the clothing of the legs. This might be done by using leggings reaching the thigh or by wearing two pairs of pants. It is found that the onset of the symptoms was gradual as a rule. A soldier would at the end of a turn in the trench suffer from slight swelling. During the resting period he recovered, but on the next occasion the symptoms became so severe that he was disabled. Such cases should be investigated by the medical staff and tested before they are allowed to return to trench duty. When the condition has become so severe as to disable the soldier he should not be allowed to walk or march more than is absolutely necessary when he leaves the trench. As soon as possible he should be conveyed to a resting-place. In many cases the records tell of disabled men having to walk back to billets some miles behind the line of the trenches. Wherever possible in such circumstances transport should be taken advantage of. When the billets are reached measures should be directed to giving the feet as much rest as possible. The feet should not be warmed in any way that causes congestion, and the return of the normal circulation should be delayed rather than hastened.

6. Succus Allii in the Control of Suppuration in Wounds.—A. D. S. Cooke and V. Gabriel have found that with lotions prepared from garlic juice and distilled water it has invariably been found, that after washing out the wound twice daily, and at the same time establishing drainage, a noticeable improvement occurs within 24 hours, and a very marked and decided improvement within 48 hours. Not only has the purulent discharge become markedly diminished, but where there has been pain this has either been much relieved or has disappeared in the same period of time, while no injury to the tissues has been apparent. The reason for employing succus allii in suppurating wounds is given as follows: One of the authors, following Minchin, had for some considerable time employed garlic juice in an inhalation for the treatment of active mixed infections in pulmonary tuberculosis with results which were often successful in overcoming mixed infection caused by the ordinary pyogenic organisms. From this it was argued that a lotion containing succus allii, if brought into direct contact with organisms within a wound, should inhibit bacterial growth and check pus formation. As previous experience had shown that a freshly prepared lotion of succus allii 1 part to distilled water 3 or 4 parts, when employed in tuberculous sinuses, did not injure tissues, it was decided to use lotions in the above strengths, washing out the wounds twice daily and maintaining where possible free drainage. The first case, the details in which the lotion, succus allii 1 part and distilled water 4 parts, was tried was a case of empyema from which a large quantity of very offensive, greenish-yellow pus was evacuated after the resection of a rib. The subsequent discharge was copious and foul-smelling, but after 48 hours it was noticed that the purulent discharge was free from odor and rapidly diminishing in amount. This was regarded as extraordinary, and it was decided to try the effects of the garlic juice lotion in other cases. The results were equally good.

7. Picric Acid as an Antiseptic.—H. L. Tidy concludes that a 0.165 per cent. solution of picric acid has the same bactericidal powers toward a culture of typhoid bacteria as has the standard 1 per cent. solution of carbolic acid. Thus the Rideal-Walker carbolic acid coefficient of picric acid is exactly 6.

3. Paroxysmal Hemoglobinuria. E. Emrys-Roberts.
4. Congenital Dislocation of Right Foot with Almost Complete Absence of Right Fibula. E. M. Sympson.

1. Acidosis in Diabetes Mellitus.—A. P. Beddard, M. S. Pembrey, and E. I. Spriggs report the results of the investigations carried on during the past twelve years at Guy's Hospital. The chief practical result of this work has been the demonstration that analyses of the carbon dioxide in the alveolar air of the lungs afford an index of the degree of acidosis as a guide in treatment and prognosis. In cases of diabetes there is a relation between the alkalinity of the serum and the amount of carbon dioxide in the venous blood; the

two rise and fall together without being actually parallel.

2. **Alveolar Carbon Dioxide Determinations in Diabetes.**—E. P. Poulton states that the object of alveolar CO_2 determinations is to measure severity of acidosis. Hence it is useless to apply the method when the urine, in a case of diabetes, gives a negative result with the nitroprusside test. Under these circumstances the alveolar CO_2 pressure will always fall within normal limits. However, when the urine contains acetone bodies, it is usually impossible, from the nitroprusside or ferric-chloride tests alone, to say how severe the acidosis is. In any of these cases the alveolar CO_2 pressure is a sure guide. By its means cases can readily be divided into two categories: (1) The mild cases, in which the alveolar CO_2 pressure falls within normal limits; in these cases the prognosis with regard to coma is relatively good. (2) The severe cases, in which the alveolar CO_2 is definitely lower than normal; here the utmost care must be taken to prevent the onset of coma. All the time the CO_2 is below normal the patient is, as it were, on the edge of a precipice, and any disturbance, such as sudden excitement or worry, or the administration of too rigid a diet, may push him over the edge. In these cases the actual CO_2 pressure observed will give the measure of the danger. A value of 2 per cent. means that coma may supervene within twenty-four hours. A value of 3 per cent. or 4 per cent. is less dangerous; in the worst event, coma will not come on for at least two or three days. A sudden drop in the alveolar CO_2 is also of significance; it means that acidosis is increasing, and, though the immediate danger may not be great, there is always the possibility of a further increase until coma sets in. This sudden drop in the CO_2 pressure may be unaccompanied by symptoms, such as drowsiness, abdominal pain, or air-hunger; for these only appear when the CO_2 reaches a very low value—that is, about 2 per cent. Hence the alveolar CO_2 gives by far the earliest warning of approaching danger. Again, it is possible to be misled if reliance is placed on symptoms alone, without determining the alveolar CO_2, because it not infrequently happens that the rapid onset of coma may be suspected from symptoms, even when the alveolar CO_2 still remains relatively high. Of course, it does not necessarily follow that the chance of averting coma is hopeless because a very low CO_2 pressure is obtained. It may be kept off for a considerable time by judicious treatment.

Berliner klinische Wochenschrift.

August 16, 1915.

Clinical and Experimental Experience with Tetanus.—Pribram, representing v. Eiselsberg's clinic, first calls attention to the relative increase of the disease in the present war. In the Crimean war but 1.5 per thousand wounded developed tetanus; in the American Civil War the corresponding figure was 2.0, in the Franco-Prussian war 3.5, while in the present conflict, in the XV German Army Corps the ratio has been 6.6 per thousand wounded. This increased frequency is set down to the vast extent of trench warfare, although infection of the soil does not extend below 30 cm. depth. The permeation of hose with dirt, the nearly frozen condition of the feet, predispose to infection of the lower extremities, in which mild as well as extensive injuries became the staring point of the disease. The conditions of peace tetanus were often inverted, as when severe cases developed after long incubation, milder ones after brief incubation. Treatment has led to most problematic results. Brilliant percentages of recovery rank side by side with highest mortality percentages. Magnesium has enemies as well as friends. Baccelli's carbolic acid treatment has been found by some quite inert. All these contradictions can mean but one thing—there is tetanus and tetanus. A unicistic view is unscientific. Statistics cannot show what remedies are good or inert. Some attempt must be made to give a status to mild tetanus, *i.e.* tetanus with fair prognosis. Every fatal case must be autopsied. Prodromes, so often present and characteristic, may often be quite absent. The disease proper begins with trismus and epigastric pain, the latter a forerunner of spasm of the diaphragm. This symptom is by no means constant, but when present is invariably of grave prognostic significance, despite the relative mildness of other symptoms. Death may even follow in a few hours. Conversely absence of this is a distinctly favorable prognostic. When present the epigastric pain is an indication for pushing narcotics. Contractions of the diaphragm are of especially grave significance when associated with spasms of the glottis, and spasms of the pharynx make up a triad of symptoms which have far more significance than trismus and opisthotonus. Thismus is practically never absent. Convulsions, when severe and universal, in the realm of voluntary muscles, naturally give a grave prognosis. In severe cases sweating may be enormous, and hyperidrosis ranks with trismus as a symptom never absent. Fulminating tetanus, with its very brief incubation period is a rather simple disease picture. Often the patient appears to succumb to toxemia, the active manifestations being relatively mild although succeeding one another rapidly. The cases with short incubation and those with the diaphragm-glottis-pharynx spasms would comprise the two types of grave or hopeless prognosis were it not for the fact that pulmonary complications cause many deaths irrespective of disease type (whether patients die from or simply with pneumonia is often a question). So common is pneumonia in tetanus cases that some authors believe in the existence of a specific tetanus pneumonia. The deadly effects of convulsions of the diaphragm appear to reside in the circulatory organs and not in pulmonary disturbances. In other words the vena cava inferior is violently compressed and stagnation results in the greater circulation. To this may be added the acute edema of the lungs which may follow spasm of the glottis. Weichselbaum has in nearly all autopsies on tetanus subjects found evidences of the status thymico-lymphaticus. Doubtless these subjects find great difficulty in the manufacture of antitoxin. This fact will do much to alter our theories of the disease. Either soldiers with this status must be kept from battle or given large doses of antitoxin before fighting.

The Limitations of Salvarsan in Syphilis.—G. Inouye and S. Hamanishi report their experience in the treatment of 1,780 cases of syphilis during the past five years. They find that whereas the conjoint use of salvarsan and mercury in early cases of syphilis was satisfactory, nevertheless 30 per cent. of these were incompletely cured or show a recurrence. In the early cases treated only with salvarsan intravenously there were 70 per cent. of recurrences and incomplete cures. In early cases treated with the subcutaneous injection of only 0.6 gram of salvarsan the results for the following three years were far better than with intravenous injection; but in advanced syphilis the results were just the reverse, recurrences taking place more frequently with subcutaneous than with intravenous injection.—*Sei-i-Kwai Medical Journal.*

Insurance Medicine.

The Influence of Height and Weight on the Mortality of Insured Persons.—Dr. A. Rabagliati says that in the large number of new facts regarding the influence of height and weight on longevity and therefore of their value in life insurance, different views may be taken and different significance seen. An important consideration seems to be that sound conclusions seem to have been drawn often from comparatively small numbers of facts, although no doubt we should be ready always to consider new facts and their bearing on the conclusions to which we ought to come.

The conclusions we have to consider regarding the influence of height and weight on mortality are based on the records of 812,221 policies on the lives of men of North America, but it was deemed advisable to eliminate the cases at the extremes of height and of ages at entry. The committee was a joint one, chosen from among the members of the Association of Life Insurance Medical Directors and the Actuarial Society of America. The policies dealt with were those of men whose ages at entry were from 20 to 62 years inclusive, and whose heights ranged from 5 feet 3 inches to 6 feet 2 inches, representing 744,672 cases, or 92 per cent. of the data submitted.

First, it is of interest to observe that out of the 744,672 men in question, only 24,525 were of average height at date of entry. This investigation showed that the average height of the men examined and accepted by the United States and Canadian life insurance offices was 5 feet 8½ inches; while that of women was 5 feet 4¼ inches. This averages about 1 in 30, and seems to show that abnormalities are very numerous. Next, no fewer than 396,034, or more than half of the cases, were at entry from 20 pounds below to 20 pounds above the average weight. Thirdly, covering the whole number of insured persons, while the expected deaths were 38,038, the actual deaths were 41,717, or 10 per cent. above the expectation. A fourth fact of much interest is that underweight appears to have far graver influences on health in early life than it does in later life. In fact, it seems to be an advantage in the latter stage of life. Thus of those entering at 20 to 24 years of age, 25 to 45 pounds underweight, the mortality actually experienced bore to that expected a ratio of 134 to 100. That is, 134 deaths occurred where only 100 were expected. On those entering at 50 to 56 years of age and from 25 to 45 pounds underweight, the actual mortality was only 91 per cent. of the expected, and among those entering at 57 to 62 it was only 81 per cent.

The influences of overweight were found to be different. A great excess of weight of from 50 to 80 pounds had a bad effect at all ages of entry, but less at early ages than at later ones. Thus this amount of overweight at entry, 20 to 24, only resulted in a ratio of 103 to 100 expected; but at ages of entry, 40 to 44, the ratio rose to 175, and at 57 to 62 it was 138 per cent. Overweight, according to the rulings of the committee, to a moderate degree, is not a serious impairment in the young at entry, but has a material effect at the middle ages. For example, in the age group, 20 to 24, the mortality among those from 50 to 10 pounds overweight was 3 per cent. in excess of the standard; while in the age group, 40 to 44, it was 75 per cent. At higher ages the effects are less serious.

The influences of height, apart from weight, are not so apparent. At 20 to 29 years at entry, men of 5 feet 3 inches to 5 feet 6 inches, showed a ratio of 96 per cent. actual deaths to 100 expected; at from 5 feet 11 inches to 6 feet 2 inches the ratio was 122 per cent. At 40 to 49 men of the same three heights showed mortality ratios of 110, 109, and 120 per cent.; at age of entry, 50 to 59, the ratios of actual to expected deaths were 108, 109, and 101 per cent. The committee conclude that at the younger ages tall men have proved less desirable risks than short men; at the older ages the short and medium-sized men have been slightly worse risks than tall men.

Dr. Rabagliati concludes by saying that if any criticism could be made on the excellent work done by the committee, it would be to the effect that the effects of height and weight on the mortality of insured persons are rather weakened so long as "vital capacity" or chest expansion is overlooked. The inculcation of deep and full respiration being one of the most important of health functions, the play of the chest in ordinary respiration comes to be an important factor and closely related to height and weight.—The Assurance Medical Society, London, March 3, 1915.

Cooperation of Medical Director and Local Examiner.—Dr. B. L. Jenkins in a paper read before the Medical Life Insurance Section of the Texas State Medical Association, says that life insurance is of dual nature—economic and spiritual, for it is found in Holy Writ that "he who provideth not for his own household is worse than an infidel" and again "out of the mouth of two witnesses all things shall be affirmed."

With these two biblical truths before us; one the strongest injunction to insure and the greatest incentive for insurance the world has ever heard; and the other a direct admonition and promise, it behooves the medical director and local examiner, each to cooperate with the other that a fair and just conclusion may be reached as to merits of the risk.

The duty of each is not alone to the company, but to the applicant as well; for so accurately have actuary and mortality statistics been calculated that the expectant period of life has been reduced mathematically, to hours. Such being true nearly all men are entitled to some kind of insurance at some rate.

It, therefore, is the duty and should ever be the practice of the local examiner to furnish to the medical director a perfect pen picture of the applicant, and it is the duty and should be the invariable rule of the medical director to study this picture as an art critic from its every angle before rendering his decision, and he should not do so then if there be any matter of doubt in his mind as to conditions or findings by local examiner, or if he does not concur in recommendations therein made, until he has again conferred with the local examiner in effort to elucidate, or obtain more light on a mooted question. And if he be inclined not to concur in recommendations he should specifically state to the local examiner his reasons for such nonconcurrence, whether they are favorable or otherwise to the applicant.

Such zealousness is owing both to the company and to the applicant and his dependents. Such cooperation is essential, for each should and does prove a check to the other; each has his function, but inseparably connected, and each is indispensable to the insurance company's success.—*Texas Medical News.*

Book Reviews.

CYSTOSCOPY AND URETHROSCOPY FOR GENERAL PRACTITIONERS. By BRANSFORD LEWIS, B.S., M.D., F.A.C.S., Professor of Genito-Urinary Surgery, Medical Department of St. Louis University, St. Louis, Mo.; Genito-Urinary Surgeon to St. John's Hospital, etc., and ERNEST G. MARK, A.B., M.D., F.A.C.S., Professor of Genito-Urinary and Venereal Diseases in the University Medical College, Kansas City, Mo., etc. With a chapter by WILLIAM F. BRAASCH, M.D., Attending Physician to the Mayo Clinic, Rochester, Minn. Two hundred and thirty-eight pages with 113 illustrations, twenty-three of which are printed in colors. Price, cloth, $4.50 net. Philadelphia: P. Blakiston's Son & Co., 1915.

As the authors state in the preface, since developments in these fields have been so rapid there has been ample room and need for the several excellent text-books on cystoscopy and urethroscopy that have appeared in recent years, and a similar demand has impelled the production of the present volume. This book gives an interesting presentation of the subject of the development and practical application of the cystoscope and urethroscope and contains much valuable information. However, it seems to us that the third and fourth chapters, entitled, respectively, "Operative Technique" and "Ureteral Catheterization," will bear expanding. The average beginner requires most explicit instruction upon points in technique and the interpretation of findings; and we also believe that more emphasis should be placed upon the difficulties and dangers of cystoscopy and the sources of error under varying conditions. These things are of vital importance to the novice, for whose enlightenment this book was principally intended.

Those sections dealing with diseased conditions of the bladder and urethra are well written and the authors are to be congratulated for having condensed a great deal of practical importance into a comparatively narrow compass. As would be expected, the chapter on ureteropyclography, by Braasch, gives a delightful summary of this phase of the subject. The authors have given a good general view of their subjects, the book is profusely illustrated and the presswork leaves nothing to be desired. All things considered it should form a useful addition to the list of books devoted to this fertile field.

THE TREATMENT OF FRACTURES. With notes upon a few common dislocations. By CHARLES LOCKE SCUDDER, M.D.; Surgeon to the Massachusetts General Hospital; Associate in Surgery at the Harvard Medical School; Fellow American Surgical Association; Member of the American Urological Association, and of the American Society of Clinical Surgery. Eighth Edition, revised with 1057 illustrations. Price, $6.00 net and $7.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS book maintains the high standard it has already reached in the seven previous editions that followed each other rapidly since the work first appeared fifteen years ago. One perceives the same effort to make the presentation of the subject matter helpful to the general practitioner, the illustrations being numerous and clear and showing particularly the different stages in the application of dressings. Many new illustrations appear in this edition. The text contains also a description of the use of autogeneous bone grafts in cases of delayed union and of non-union; and new material upon fractures of the jaw, the acetabulum, the greater tuberosity of the humerus, and upon separation of the lower epiphysis of the femur. The author rightly maintains the conservative attitude that operative treatment is not to be undertaken lightly.

EVOLUTION AND DISEASE. By J. T. C. NASH, Captain, R.A.M.C., T.F., S.S.; Diplomate in Public Health, University of Cambridge; Doctor of Medicine, University of Edinburgh, etc., etc. "Nec scire fas est omnia." Price $1.40 net. New York: William Wood and Company, 1915.

THIS book is based upon the three Chadwick lectures delivered by the author in 1913. The subject matter is divided into sixteen chapters the first three of which deal with the history of medieval epidemics and the remainder with the evolution of epidemic disease. The Chapter headings are as follows: Famine and Pestilence in the Middle Ages; Medieval Psychopathic Epidemics; Medieval Plague—The Black Death; Evolution of Pathology; The Sweating Sickness and Influenza; Measles and Smallpox; Malignant Fevers; Insanitation an Evolutionary Factor; General Remarks on Specificity and Evolution in Disease; Science and Philosophy as Applied to Evolution; Heredity and Disease; The Declension of Phthisis; Present-Day Evidences of Evolution; Further Bacteriological Evidence of Evolution; The Evolution of Disease and Disease Germs; The Evolution of Sanitation; War as a Factor in the Evolution of Epidemics. The last chapter has a special interest at the present time. The book is an interesting and scholarly excursion into the history and philosophy of medicine.

DIE OPERATIONSFREIHEIT IM LICHTE FORTSCHREITENDER STRAFRECHTSREFORM. Eine kritische Betrachtung zum Entwurfe eines Deutschen Strafgesetzbuchs von Dr. HANS LIESKE. Preis 60 pfg. Berlin: August Hirschwald, 1915.

THE right of the surgeon to operate on minors without the consent of the parents or guardians is naturally of vital importance to the operator because if the patient dies without operation the surgeon may be accused of negligence. The same holds good for operations on the insane and adults temporarily irresponsible. The author sums up the entire question in this brochure in a few words. If a physician treat professionally a patient over the age of 18 years against his consent, the law should punish him. If the age of 18 years has not been reached, the consent of the patient's legal representative must be obtained. This representative should also have a voice in the appointment of a custodian for an insane or feeble minded person, provided the latter possesses sufficient intelligence to form a judgment on his status.

THE OPERATIVE TREATMENT OF CHRONIC INTESTINAL STASIS. By Sir W. ARBUTHNOT LANE, Bart., M.S., F.R.C.S., Senior Surgeon to Guy's Hospital, and Emeritus Surgeon to the Hospital for Sick Children, Great Ormond Street. Third edition. Pp. 201, with 102 illustrations. Price, cloth, $4.00. London: James Nisbet & Co., Limited, 1915. Chicago Medical Book Company, American agents.

IN the two preceding editions the title "Chronic Constipation" was employed instead of "Chronic Intestinal Stasis" because, as the author says, the delay in the large bowel is the primary or causal factor of the condition, and the title "Chronic Constipation" at that time called for less explanation than that which he has now rendered familiar to the profession. While for many years intestinal stasis, by one name or another, has been recognized as a potent factor in the causation of many ailments, Mr. Lane long ago became imbued with the idea that this was a far more common etiological factor than the profession at large realized. Whether or not one agrees with Mr. Lane, either in his views as to the origin and development of the various factors which ultimately bring about intestinal stasis, or the extent of damage which it is capable of inflicting upon the individual, or in the drastic operative procedures which he recommends, one must admire him for his dogged persistence in enunciating his views in the face of initial scepticism and much subsequent adverse, and sometimes none too friendly, criticism. He has certainly shown that he has the courage of his convictions; and it cannot be denied that the intensive study of intestinal conditions, which was stimulated by the exposition of his theories and made possible by improvements in *x*-ray technique and greater skill, born of experience, in interpretation of *x*-ray findings, has resulted in a broadening of our knowledge and a much better appreciation of the potentialities for good or evil of the intestinal tract..

In this book we have a clear exposition of the studies, impressions, deductions, which led Mr. Lane to the formulation of a working theory, and a recital of experiences which finally led to the adoption of his present views on intestinal stasis and convinced him of the necessity for the surgical measures which he recommends. This material is comprised in the first, fifth and sixth chapters, covering about 175 of the 201 pages, and much of it is of absorbing interest. The other three short chapters are: "The Investigation of Chronic Intestinal Stasis by the *X*-rays," by Alfred C. Jordan, M.D., M.R.C.P.; "The Bacterio-Chemistry of the Small Intestine," by Dr. Nathan Mutch, and "*X*-Disease: An Extract from 'Diseases of the Heart.'" by Dr. James Mackenzie.

All who are interested in getting accurate, first-hand knowledge of Lane's ideas on the subject of chronic intestinal stasis will do well to read this book.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 23, 1915.

THE SECRETARY, DR. GEORGE W. KOSMAK, IN THE CHAIR.

THE program of this meeting was contributed by the members of the staff of Mt. Sinai Hospital.

Report of Three Cases of Fibroids Complicated by Carcinoma of the Intestine; Resection; Recovery.—Dr. JOSEPH BRETTAUER reported these cases. He said the first case was one of fibroid of the uterus complicated by adenocarcinoma of the sigmoid. The latter condition was accidentally discovered during the operation for fibroid. The sigmoid was resected to the extent of about four inches. The proximal end was pulled through the remaining part of the rectum and fastened at the anus. The pelvic peritoneum was closed entirely. The patient made an uninterrupted recovery, with full control of the sphincter ani, and three years after the operation was perfectly well. The second case had been reported in the *American Journal of Obstetrics*, 1909, Vol. 60, "Transactions of the New York Obstetrical Society." This patient was operated on for suspected malignant ovarian neoplasm. On opening the abdomen the mass proved to be a solid growth originating from the meso-sigmoid close to its attachment to the gut; down along the sigmoid two more nodules were felt. After a supravaginal amputation of the fibroid uterus, the sigmoid was resected, the proximal end being drawn through the rectal end and fastened at the anal orifice. A stormy convalescence followed due to difficulties encountered in overcoming the strictured portion of the anastomosis. In view of the pathologist's report of round cell sarcoma of the mesentery and metastases in the mesentery and in the intestinal wall, steps for radical relief were not considered. The operation was performed in December, 1912, and on February 15, 1915, the patient's condition was excellent. There was a metastatic swelling the size of an egg in the tenth intercostal space, the nature of which was somewhat suspicious. Excision was not thought of, as, if this was a metastasis, there were undoubtedly others situated elsewhere. The third patient, 41 years of age, sought relief because of retroflexed uterus and enlarged, adherent, and tender appendages, the left of which apparently contained fluid. On opening the abdomen the sigmoid flexure was found covered with dense adhesions which formed a tumor-like mass about five inches in length. This proved to be a well shut off abscess cavity caused by the perforation of an adenocarcinomatous ulceration in the lower sigmoid. This was freed, resected, and an end-to-end anastomosis established with a Murphy button. The right ovary was found tightly adherent and carcinomatous. The entire posterior surface of the uterus was covered with necrotic masses, and here and there small metastases were noted. The left appendages presented the appearance of a tuboovarian cyst which was tightly adherent. There were indurated areas in the pelvis which were beyond the possibility of removal. This patient improved for a time, but four months after the operation began to show symptoms of stricture of the rectum, which necessitated the establishment of an artificial anus a few weeks later. The benefit of the artificial anus was only temporary; the patient died within two months from the time of the second operation. These cases were reported because of the absence in all of them of any symptoms pointing to intestinal disease. In all three cases this complication was found in operating for another cause. A study of the histories, even after the actual state of affairs was known, elicited no symptoms pointing to the true condition. As to the methods of establishing intestinal anastomosis, time was of importance in all three cases; the method employed in the first two required the least time. In the third case he used the Murphy button, which could also have been used in the others.

Dr. TAYLOR recalled that some years ago when he assisted Dr. Tuttle they frequently found these conditions of the sigmoid and sometimes they treated them in unusual ways. In one such case in which they did not wish to lose time the choice lay between an artificial anus or joining the portion of the sigmoid to the top of the vagina. The latter procedure was chosen. The patient made a good recovery. She had one movement daily, after which the vagina was washed out. She had no trouble whatever from the movement passing through the vagina.

Vaginal Subtotal Hysterectomy for Procidentia and Large Cystorectocele Associated with Chronic Fibrosis Uteri.—Dr. HIRAM N. VINEBERG reported this case which he operated upon after a method somewhat different from that usually employed in such cases. He stated that it was well established that vaginal fixation, or the more recent term, interposition, fulfilled the object in view in most cases of procidentia and large cystorectocele, when the climateric was near at hand, or when the woman had already borne a good sized family and further pregnancy might be eliminated. But the operation called for a fairly normal uterus. If the uterus was very large because of the existence of fibroid nodules or diffuse fibrosis, or was exceedingly small through senile atrophy, it was contraindicated. The same applied to the uterus, which, though normal in size, was the subject of uncontrollable hemorrhage. After speaking somewhat in detail of the operations at present in vogue for the correction of procidentia and large cystorectocele, he described a vaginal method which he had been employing for over three years. This method consisted in amputating the body of the uterus fairly high up and utilizing the cervical stump as a pelotte to hold up the bladder. When the woman was still comparatively young, and the creation of an artificial menopause might seem undesirable, the amputation might be done so high up as to leave, together with the adnexa, the lower segment of the uterus with a corresponding area of endometrium. Not infrequently a difficulty presented itself in that the vaginal portion was very much hypertrophied and elongated, or badly lacerated with considerable eversion of the cervical mucosa. Where such conditions were present it had been his custom to amputate the lower portion of the cervix, leaving only a comparatively short cervical stump, extending from the vaginal vault to the lower uterine segment, and using this to support the bladder. After the redundant vaginal flaps were resected to the extent that the individual case required, the cervical stump was sutured to the subpubic fascia and to the anterior vaginal wall. The bladder was then forced to take a position within the abdomen and its prolapse was prevented by the firmly fixed cervical stump. The operation was completed by doing the necessary operation upon the posterior vaginal wall and the perineum. Dr. Vineberg said that thus far he had performed this operation ten times. Two of the operations had been done during the past two months and therefore had to be excluded for the present so far as results were concerned. Of the other eight cases, one had been under observation for three years and three months; two for twelve months; two for fifteen months, and three had been lost sight of. The results in all the observed cases were excellent from the anatomical standpoint, except in one. This patient continued to complain of a bearing down feeling and frequent micturition, though there was no recurrence of the cystocele, but the vaginal portion of the cervix came down to the introitus. In this instance it would have been wise to have done a partial amputation of the cervix, as had been done in some of the other cases with long and hypertrophied vaginal portions. Dr. Vineberg reported the following case as an illustration of the value of this procedure. The patient, 23 years of age, had had an abdominal supravaginal hysterectomy done in an out-of-town hospital sixteen months before she was admitted to Mt. Sinai Hospital. A few months after this operation everything came down as before. At the time of admission to the hospital the long cervix with bladder and rectum protruded from the vagina. At operation the anterior vaginal wall was incised from the urethral meatus to near the cervical os; the bladder was dissected away from the cervix and broad ligaments. On opening the peritoneal cavity a long fibrous band was found stretching from the cervical stump to the abdominal wall. This was severed. The redundant vaginal flaps were excised and after the cervical stump was shortened by a liberal excision of its lower part, it was sutured to the subpubic fascia and to the vaginal wall as described above. The operation was completed by a suitable posterior colporrhaphy. Seven months after the operation the result was simply perfect. The cervical stump was high in the vaginal vault, both vaginal walls were in apposition, and when the patient bore down there was little protrusion of the anterior vaginal wall.

Dr. J. RIDDLE GOFFE said he had had no experience with the method described by Dr. Vineberg, but he would like to ask him what he did about controlling the blood supply, and how he disposed of the bladder. Did he put it on top of the cervical stump and leave it to take care of itself, or did he stitch it in some definite position? One should not deceive himself into believing that the cervix held up the bladder. The cervix in this instance was simply the insertion of the cardinal ligaments. It was the ligaments that afforded the cardinal support. It seemed to him that it was preferable to get rid of the old infected cervix and utilize the ligaments exclusively for this support as in the operation for cystocle which he had devised and which was known by his name.

Dr. VINEBERG, in reply to Dr. Goffe, said that he left a cervical stump and a sufficient blood supply. He had not mentioned the blood vessels because he took for granted that they understood that vessels were ligated as was usually done. Dr. Goffe implied that the nutrition of the cervical stump would suffer. There was no need for such fear as the technique was similar to that of an abdominal supravaginal hysterectomy, the only difference being that this operation was done through the vagina. The bladder was disposed of in the same way as in the interposition operation. All could not perform Dr. Goffe's operation as successfully as he could. For himself, he had some hesitancy in suturing the bases of the broad ligaments. Looking at the field from above after a panhysterectomy one could see that to suture the lower part of the broad ligaments together would bring about considerable tension and this was not desirable. Where the cervix was hypertrophied or deeply lacerated, he amputated the lower portion, leaving only a short stump extending from the vaginal vault to the lower uterine segment, and he used this to support the bladder.

Dr. ARNOLD STURMDORF said that when gynecologists of Dr. Vineberg's experience found it necessary to devise new methods for the cure of cystecele, it became evident that prevailing methods were unsatisfactory in results. Just so long as operaters continued to center their conceptions and precedures upon supporting elements and ignored the mechanism of displacing factors, so long would they fail to cure many cases of bladder prolapse. The bladder had no true ligamentous support; its fascial and ligamentous equipment was only one element in the perfect mechanism that counteracted the expulsive force of intraabdominal pressure, not by textural resistance, but by deflecting the direction of intraabdominal pressure toward the normal pelvic outlets. The musculature of the pelvic floor and the mobile uterus presented a complicated deflecting mechanism and in order to restore and maintain pelvic topography these elements must be restored to normal position and function. Any attempt to anchor the bladder in abnormal positions was unsurgical, unanatomical and futile. In the so-called interposition operation, the bladder, fortunately for the operator, often slipped back into its normal position and when it did not failure ensued; its permanent fixation above and behind the fundus was a physiological impossibility. Dr. Goffe's operation fixed the bladder in its normal position and hence it was superior to and in advance of other methods.

Dr. HENRY DAWSON FURNISS expressed the opinion that, if most of the patients with prolapse and big hypertrophied cervices and uteri were put to bed and given douches for three weeks to a month, it would not be necessary to amputate the cervices and fundi of the uteri before doing an interposition operation. By such treatment the edema of the surrounding structures would disappear and the operation would be technically much easier. He called attention to bladder trouble subsequent to these operations, and said he had known of instances of the infection extending to the kidneys, and of one death due to such a cause. He disagreed with Dr. Sturmdorf as to the position of the bladder. In examining many such cases after operation he had always found the fundus uteri under the trigonum, lifting it up. The ureters opened on either side of this elevation.

Dr. TAYLOR said that Dr. Vineberg had brought out one point and that was that in attempting to do an interpositien operation, where the uterus was too large, there were three ways of meeting the difficulty. It was of practical importance to leave organs in their anatomical relatien and to endeavor to cure symptoms; to this end it might be satisfactory instead of interposing the entire uterus to fasten the anterior surface of the fundus to the vaginal wall and follow that by ventral fixatien. He assumed that the abdominal wall would support the uterus and had attached it to that with good results.

Dr. VINEBERG, in closing the discussion, said that according to Dr. Sturmdorf's theories no good results ought to be expected from this procedure which he had described, but that good results did occur nevertheless. With regard to keeping the patients in bed for a while before they were operated upon, in the wards of hospitals this could be done better than with private patients. It might be pointed out, however, that the involution spoken of did not take place in cases of fibroids or fibrosis. In all cases the method of treatment was a matter of selection. One should not leave an organ that gave rise to nervous symptoms and there was no pelvic condition more fruitful of manifold nervous disturbances than a uterus in a state of chronic metritis or fibrosis. With the operation he had described he had secured perfect anatomical results and relief from symptoms.

Intraperitoneal Hemorrhage of Unknown Origin.—Dr. ROBERT T. FRANK presented this report. He stated that this was the third case which he had encountered in which, on opening the abdomen, a large intraperitoneal hemorrhage was found, the source of which was never determined. The patient was 23 years of age and single. Her menstrual history had been normal until about a year ago when dysmenorrhea and menorrhagia developed. Three days before admission to the hospital there was an acute attack of abdominal pain and faintness. The bowels were constipated and urination painful and frequent. At the time of admission the patient looked very ill. The temperature was 105° F. and pulse 120. A large hard tumor was felt in the right hypochendrium, reaching to the umbilicus. The uterus could not be outlined. A diagnosis of ovarian cyst with twisted pedicle was made. A laparotomy was performed immediately and a large amount of fluid and cletted blood evacuated. The tumor proved to be a firm fibroid of the uterus. The adnexa were normal. A thorough inspection of all the viscera revealed nothing abnormal except some jelly-like deposits on the intestines. Rapid supravaginal hysterectomy was performed together with the removal of the right adnexa. The specimen removed shewed a hard fibroid with tuberculosis of the endometrium and ovary. A pin point opening on one of the veins of the fibroid which was supposed to be the source of the hemorrhage was found to be traumatic, that was made at the time of operation.

Dermoid Cyst of the Ovary with Carcinomatous Change.—Dr. ROBERT T. FRANK reported this case. He stated that only about 40 cases of this nature had been reported in the literature. The patient, 50 years of age, had been told nineteen years before that she had a tumor. The menepause had occurred six years before. She had had no children, but two abortions. The abdomen was prominent, lax, and contained a tumor in the median line, extending to half way between the xiphoid and the umbilicus. A diagnosis of ovarian cyst was made. At laparotomy a right ovarian cyst the size of an adult head was removed. This cyst contained hair and sebaceous matter. At one pole was a thickened area, gelatinous in consistency, with putty-like inclusions. Microscopical examination by Dr. F. S. Mandlebaum showed carcinomatous areas in the dermoid. Some months later the patient was readmitted to the hospital with symptoms pointing to lung and vertebral involvement (confirmed by *x*-ray). No response to recent inquiries could be obtained.

Cesarean Section Necessitated by Large Gartner Cysts.—Dr. ROBERT T. FRANK reported this case. This patient presented herself in August, 1913, when she was seven and one-half months pregnant, because of a large protrusion from the right buttock and a feeling of fullness in the vagina. Examination showed a large cystic mass which caused the right buttock to protrude three inches beyond the left and encreach greatly on the pelvic cavity. Above the large cyst was another the size of an orange, extending to the premontory. As labor through the natural passages was not possible the child was delivered by cesarean section at term, and five months later the mother presented herself for the removal of the cysts. A large cystic mass the size of a small grape fruit was found in the buttock, pushing the right and posterior vaginal walls inward. Above this was a cyst the size of a walnut. The tumors were smaller than during pregnancy and veins in the vagina which were distended and varicose

had disappeared. The patient was later readmitted because of complete prolapse, and on examination a cystic mass the size of a lemon was discovered behind and to the right of the vagina. Either a small cyst had been overlooked or this had grown in the interval. The cyst intimately adherent to the right lateral and posterior rectal walls was removed after the fibers of the right levator ani were cut across. The dissection had to be carried up to the peritoneal reflection, and the lower four inches of the rectum had to be mobilized as for a resection of the rectum. The operation was completed by a large Hegar denudation and a typical colpoperineorrhaphy. The patient had since remained cured. Dr. F. S. Mandlebaum had reported that the cysts were composed of fibromuscular wall, lacked definite epithelial lining, and probably originated from Gartner's ducts. Cysts of this nature did not ordinarily attain sufficient size to obstruct labor or to cause technical difficulties in their removal.

Dr. GEORGE W. KOSMAK asked if there was any possibility that the hemorrhage had come from a corpus luteum. A case had been reported at a recent meeting in which, after a prolonged search, a corpus luteum was found to be the source of hemorrhage.

Dr. FRANK replied that the bleeding had not come from a corpus luteum; they had searched every viscus, even the pancreas, and failed to find the bleeding point. It seemed that every possible source of hemorrhage had been excluded. He recalled a somewhat similar case in which the source of the hemorrhage could not be located. At autopsy colored solution was run through the circulation and even then nothing could be found.

As to dermoid cysts becoming carcinomatous, it had been stated that 1 per cent. of dermoids became malignant. These cases should not be looked upon as benign, even though the cancer was within the cyst, since there was danger that metastasis might occur.

Large Hydrosalpinx. — Dr. SOLOMON WIENER presented this specimen of hydrosalpinx which before operation had been diagnosed as an ovarian cyst. He said that the specimen showed why the mistake in diagnosis had been made.

Ampullar Pregnancy.—Dr. WIENER presented this report. He stated that the patient was 26 years of age, married five years, the mother of three children, the last born one year ago. Menstruation began at the age of 14 years and was of the four-week type lasting from six to seven days and painful. Seven weeks ago the patient had had a normal menstrual period, but instead of stopping there had been spotting for four weeks. She had suffered only slight pain. She had been curetted four weeks ago but continued to flow. She had had some pain in the left side for two weeks after the curettage, but this had subsided. She had never had chills or fever. The bowels and urination were normal. Physical examination showed the pulse 88 and temperature 100° F. The abdomen was soft, the uterus slightly enlarged, and a small soft mass to the left of the uterus. A diagnosis of ectopic gestation was made. At operation, twenty-four hours after admission to the hospital, the uterus was first explored and found empty. An anterior vaginal celiotomy was done, the left tube and ovary being delivered into the vagina and resected. The tube was adherent at its fimbricated end to the wall of the pelvis and contained a small ampullar pregnancy. The ovary was the site of a cyst the size of a large plum. This was ruptured in delivery. The right adnexa were normal. The wound was closed without drainage and recovery was uneventful. The points of interest were the ovarian mass which was taken for an ectopic pregnancy, whereas the actual ampullar pregnancy had not been palpated; the sealing off of the end of the tube against the pelvic wall which prevented tubal abortion; the absence of amenorrhea and the slight amount of pain. In referring to the limitations of the vaginal route, Dr. Wiener said that in this type of case in which there was only a slight enlargement of the tube the vaginal operation was the ideal procedure. He had done a vaginal salpingectomy for ectopic gestation in a number of cases; the patients showed no more reaction than after a simple curretage and were spared the discomforts following laparotomy, as well as the shock of that procedure. Whether more advanced cases of ectopic, or cases with extensive bleeding, should be operated *per vaginam* was a question which he felt must be answered in the negative. In reply to Dr. Vineberg's question as to why the ovary was removed in the second case, Dr. Wiener said that the ovary was not normal and contained a cyst the size of a plum; it was enlarged. The other ovary was normal and that was conserved.

A Case of Foreign Body in the Uterus; Infected Abortion.—Dr. WIENER also reported this case and presented the foreign body, which was a tightly wound and compressed cylinder of cotton three and one-half inches in length and about a quarter of an inch in thickness when removed. The patient, believing herself pregnant, had been taking "ergot apiol," but denied all instrumental interference by herself or anyone else. On the day upon which Dr. Wiener was called in consultation she had a temperature of 105.4° F. and a pulse of 120. In spite of this high temperature she did not appear gravely ill. The uterus, enlarged to a two months' pregnancy, was dilated without anesthesia and its cavity gently cleaned out with the curette. The first thing brought away was this foreign body and then a foul necrotic ovum. No attempt was made to curette the uterine cavity thoroughly or remove the entire decidua because of the danger of opening lymphatics and spreading infection. A hot intrauterine irrigation was given and the vagina only loosely packed with gauze. The patient made a rapid recovery. Evidently the high temperature was due to sapremia and not to a virulent spreading infection. When confronted with the foreign body the patient admitted having introduced it herself four days previously when it accidentally slipped from her grasp.

Tubal Gestation Complicated by Pernicious Vomiting.—Dr. S. H. GEIST presented this report which was of interest because of the unusual clinical history and the course of the disease. He stated that he had been unable to find any mention in the literature of pernicious vomiting and jaundice in an unruptured living tubal pregnancy. This patient, 32 years of age, was admitted to the service of Dr. Brettauer, October 15, 1914. Three years before she had had a left salpingectomy for tubal pregnancy. The last regular menstrual period was two months before. Four weeks before admission to the hospital she began to vomit, at first only in the morning, but gradually with increasing frequency until she was vomiting from ten to fifteen times daily. For the past two weeks she had had some irregular uterine bleeding. Local examination showed a softened cervix and a slightly enlarged, movable uterus with a soft mass the size of a lemon at the left cornu; to the right and high up an indefinite cystic mass was felt. A week after her admission the patient was operated upon. The uterus was found empty, but at the left cornu an intramural fibroid was found. The cystic mass of the right proved to be an unruptured, living, eight weeks, tubal gestation. The tube was removed, the myoma enucleated, and the patient promptly stopped vomiting. She made a rapid recovery except for a mild femoral phlebitis. Examination of the urine showed an excess of nitrogen, indicating an intense acidosis. It was also shown that there was disturbance of the liver function. Starvation was probably responsible for both the acidosis and the liver condition. It was the consensus of opinion that pernicious vomiting of pregnancy was due to a toxic substance elaborated by the fetal metabolism. One could feel certain that in this case the theories implicating the uterus, such as overdistention, malposition, laceration, etc., did not find confirmation.

Chorioepithelioma.—Dr. S. H. GEIST presented this report of chorioepithelioma of the uterus occurring three and a quarter years after the last pregnancy. Various cases had been reported in which a relatively long period of latency had existed, in fact one case had been reported in which eighteen years after the last pregnancy chorionic villi were found in the vein. These tumors varied greatly in malignancy, but as up to the present time they were unable to say which type would prove malignant and which benign, and for the sake of safety, every case definitely diagnosed should be operated upon. Dr. Geist said that this patient, 46 years of age, had menstruated regularly until a year ago, when the flow became irregular and rather profuse. Her last child had been born three and one-quarter years ago, and she had had a miscarriage eleven years before. She had been curetted without relief. At the time of admission to the hospital she was bleeding. The uterus was enlarged and irregular with a distinct nodule the size of a pigeon's egg at the left cornu. A diagnosis of fibromyoma of the submucous variety was made and a vaginal hysterectomy performed. The specimen showed the uterus 8.5 cm. in length, the cavity somewhat dilated and a reddish polypoid growth about the size of a grape fruit in the left cornu. The tumor was friable, non-encapsulated, and hemorrhagic in char-

acter. Histological examination showed it to be a chorioepithelioma. The convalescence was uneventful and up to the present time, fifteen months after the operation, there had been no recurrence.

Dr. STRONG said that Dr. Geist's last case was interesting histologically as having some bearing on malignancy. There were cases in which secundines were retained for many years after a miscarriage, and it might be that villi or wandering cells would, after a long time, give rise to chorioepithelioma which became malignant.

Dr. ABRAHAM RONGY said that in the first case the toxemia must have arisen from the products of conception since there was no disturbance of the uterus from pregnancy in the tubes. The kidney disturbance was a secondary manifestation. If they supposed that they had an ectopic pregnancy, would this case not have reacted to the Abderhalden test? As to the case of epithelioma, he had discovered three cases of chorioepithelioma accidentally while operating for other conditions. If, after a woman had miscarried, there was sudden hemorrhage, atypical in character, it was well to bear in mind the possibility of chorioepithelioma.

Dr. VINEBERG asked why in the case of pernicious vomiting they had waited a week before interfering. These cases of pernicious vomiting were very treacherous and one ought not to go on waiting, but should empty the uterus promptly as soon as the conclusion was reached that one was dealing with that complication. As to chorioepithelioma, he had had ten cases. This condition developed more frequently after hydatid mole than after anything else. A profuse hemorrhage after a miscarriage or a hydatid mole should arouse suspicion of chorioepithelioma. At times the clinical history and the local findings were sufficient to justify a diagnosis of chorioepithelioma, and were more reliable than the microscopic findings.

Dr. S. H. GEIST, in closing the discussion, said that he agreed with Dr. Strong as to the difficulties in making a positive diagnosis of chorioepithelioma from curettings, and that in borderline cases in which a placental polyp had existed the microscope often could not make an absolutely correct diagnosis. In the case reported there was an infiltrating tumor present which involved the entire thickness of the uterine wall. The patient had not been curetted and was not suspected of having chorioepithelioma. The speaker considered the Abderhalden test unreliable as he had worked with it for a year and a half in conjunction with Dr. Epstein. They had diagnosed pregnancy in this patient so the test could not have added any information. The operation had been delayed to ascertain by dietetic measures whether the vomiting was due to neurosis or to toxemia.

SECTION ON SURGERY.

Stated Meeting, Held May 7, 1915.

Dr. C. A. MCWILLIAMS IN THE CHAIR.

Partial Gastrectomy for Carcinoma One Year After Gastroenterostomy.—Dr. V. GAUDIANI said that while, according to Dr. Wilson's paper from the Mayo clinic, 60 per cent. or more of the malignant tumors of the stomach gave pathological evidence and clinical histories of pre-existing ulcer, on the other hand it had been proven that after gastroenterostomy for chronic ulcer without excision, cancer developed very rarely. Indeed, from the large material at the Mayo clinic, it was shown that only in four cases this had happened. Very recently Professor Vüttner of Breslau stated that out of 120 cases of gastroenterostomies done for ulcer, regarding which he was able to make post-operative inquiry, only two died from cancer. Without discussing this apparent contradiction it seemed to him rather important to refer to a case which was resected one year and a half after a gastroenterostomy for ulcer. The patient was forty-six years of age and was treated for syphilis fourteen years ago, taking regular treatment for some time. Four years ago he was seized with an attack of acute abdominal pain which appeared periodically, both day and night. It took the character of an aching pain across the upper part of the abdomen, with flatulency and a sense of burning. These attacks of pain had no relation to the meals and never occasioned vomiting. The severity of this pain, however, was such that he was obliged to use morphine and warm alcoholic drinks. In October, 1913, a posterior gastroenterostomy was performed by a surgeon outside of this city. This seemed to relieve him only slightly and for a short period of time. When he returned to his home the condition was practically the same as before the operation. He spent a very miserable life for another year, helped only by the use of morphine. In November, 1914, an exploratory operation was performed which revealed a carcinoma which proved to be inoperable. In March, 1915, he happened to come under the care of Dr. Gaudiani, and after a careful study of the patient's history and his condition, having personally witnessed the nature of the attacks, he thought that probably there had been a wrong appreciation of the anatomical and pathological conditions. As the patient asked insistently for surgical aid, refusing any examination, he was operated on on March 14. The *x*-ray picture showed a growth in the lesser curvature of the stomach. At this operation there was revealed a growth, the size of an orange, in the prepyloric part of the stomach and this invaded the lesser curvature. The lymph glands were not much involved except those about the lesser curvature and the pyloric group. The resection was not difficult excepting for the work on extensive inflammatory adhesions of the posterior surface of the pancreas. The operation performed was the typical Billroth No. 2. All of the lesser curvature was removed and the major curvature was resected. At the end of this operation another gastroenterostomy was made because the other one seemed to have narrowed. The patient made a very good recovery and now was in comfortable health and did not require the use of morphine. The specimen consisted of portion of the stomach wall which was the site of an ulcer measuring 5-5 cm. The upper surface was smooth, slightly excavated and covered with a thin layer of necrotic tissue. The floor was thin and indurated. The edges were well defined and the mucous membrane of the surrounding portion of the stomach wall was adherent to the floor of the ulcer at this point. A cross-section through the floor of the ulcer showed, after formalin fixation, a dense white surface measuring 1-1.5 cm. in thickness, extending down to the peritoneum which was much thickened. Elsewhere the mucous membrane of the stomach was markedly thickened. There were but few glands present in the specimen and these were slightly enlarged. In external appearance and on cross-section they presented nothing unusual. The microscopical examination showed the lesions of an infiltrating small cell carcinoma, while in some areas there was the typical picture of an adenocarcinoma. There was evidence of a chronic inflammation in all of the parts examined. In some there was only evidence of a thick cicatricial tissue, without epithelial invasion. The invasion of the new growth could be demonstrated in the examination of the lymph nodes. The practical teaching of this case was that already given out by MacCarty: "Whenever the clinician felt positive of the clinical diagnosis of chronic gastric ulcer, he should consider that cancer could not be ruled out by their present methods of clinical investigation." This meant that resection of the indurated, so-called "calloused" ulcer, ought to be performed every time when it was possible.

Empyema and Abscess of the Lung.—Dr. ANTHONY HART HARRIGAN presented a patient who was admitted to the medical ward of Fordham Hospital October 19, 1914. She was nineteen years of age, a stenographer. Both her parents were living and in good health. She had three sisters and one brother, all well. She began to menstruate at the age of fourteen; the menses were always painful and lasted about seven days. Four weeks before admission she was operated upon at one of the local hospitals for enlarged tonsils and adenoids, and her present illness dated from that time. Two weeks ago she had to go to bed because of severe, cutting pain in the right side of her chest. Her family physician diagnosed the condition as pleurisy with effusion and advised that she be removed to a hospital, which was done. On admission the examination revealed a pale, weak, poorly nourished young woman. The examination of the chest disclosed the classical signs of fluid in the right chest. The temperature was 103° F., pulse 120, and respirations 46. Two days after admission the exploring needle showed fluid which was purulent. The next day the patient was transferred to the second surgical division of the hospital. Through the courtesy of Dr. Willard P. Healy, the patient came under Dr. Harrigan's care. Operation was performed on October 24, 1914, under ether. A thoractomy on the right side was done. A portion of the seventh rib was

removed in the posterior axillary line and a large amount of fluid was evacuated from the pleural cavity. The cavity was properly drained according to the usual methods. Staphylococci were isolated from the pus. During the first few days after the operation the patient did well. On the fifth day her temperature rose, and she complained of pain in the wound. On the seventh day the suction apparatus was used to aid drainage. Following this the temperature became somewhat lower. Examination of the left side of the chest gave negative results. On the twenty-eighth day after the operation the temperature reached 103° F., having ranged in the meantime between 99° and 102° F. This high temperature continued until the thirtieth day, when the patient began to lose ground rapidly. She developed a cough. Examination for tubercle bacilli was negative, as was also the x-ray examination. The patient appeared profoundly septic. On December 4, 1914, forty-one days after the operation, it was noticed that there was a putrefactive odor to the patient's breath, the cough had increased, and she was expectorating small purulent masses with a strong fetid odor. Abscess of the lung was suspected and Dr. Arthur S. Unger made an *x*-ray examination which confirmed this suspicion; he stated that the abscess was deep seated. An immediate operation was done under ether narcosis. The thoracotomy wound was enlarged and the empyema cavity explored. There was no evidence of retention and the cavity was comparatively small. At the bottom of the wound could be seen the lung enjoying a fair amount of respiratory movement. A medium sized hemostat was pushed into the lung and upon withdrawal was followed by an escape of blood and air. Finding no pus at this level a long, straight, broad ligament clamp was introduced again for several inches. Upon removing this a large amount of pus escaped. A finder was introduced into the cavity and the opening into the lung was well dilated. The cavity was of goodly size and corresponded at least to the lower lobe. It was packed with plain gauze. A staphylococcus was isolated from the blood. The patient made a slow but steady convalescence. The gauze was gradually removed. The cavity closed and had remained so. In January, 1915, the patient developed a cough and examination of the sputum showed the tubercle bacilli. The patient was sent to Otisville, where she remained for two weeks, and was then discharged as repeated examinations failed to confirm the finding of the tubercle bacilli and the physical examination was negative. Dr. Francis Carter Wood explained these apparently contradictory results very easily. He stated that in his experience with abscess or gangrene of the lung one could quite easily recover organisms in the sputum which simulated clearly in staining qualities the tubercle bacillus. He believed these were closely allied to the smegma bacillus. Hence one might conclude that tuberculosis played no part in this case. The patient at present was well and had gained twenty-nine pounds in weight.

End to End Suture of the Hepatic Duct.—Dr. DEWITT STETTIN presented this case. He threw on the screen an illustration showing the normal relations of the cystic artery to the cystic and hepatic ducts as Callot had described them, stating that this arrangement was by no means invariable. The cystic duct might run parallel to the hepatic or even make a spiral turn behind it. Ruge estimated the cases of parallelism as high as 33 1/3 per cent. He had recently seen a case in which the ducts were in such close apposition that the hepatic duct was accidentally ligated and transversely divided in the course of a relatively simple cholecystectomy. This accident had happened to others though the literature on the subject was very meager. He presented this patient to show what could happen during cholecystectomy when one least expected trouble, and to point out a way of avoiding the accident, and, if it did occur, how the damage could be repaired. This patient was sixty-four years of age and gave a very characteristic history of gall-bladder disease, which had been going on for ten years. She had had six children and had been a constant sufferer from indigestion. On April 27, 1914, Dr. Stettin said he exposed the gall-bladder region through the right rectus incision. A small, somewhat thickened gall-bladder was found adherent at its fundus to the duodenum which contained one small, rounded stone. The ducts were free. In separating the gall-bladder from the duodenum he found a fistulous communication between them. When the gall-bladder was freed the small opening in the duodenum was closed with a single purse-string suture of silk. He then went ahead with the cholecystectomy in the usual fashion, beginning above. This was by no means exceptionally difficult. After separating the gall-bladder from its bed in the liver he passed the usual ligature around what he took to be the mesentery and divided with his scissors the tissue distal to the ligature. He was much dismayed to find a gaping lumen of about ½ cm. in diameter in these tissues. Suspecting what he had done, he removed the ligature, caught the artery separately, ligated it, and placed a tampon against the proximal lumen of what was undoubtedly the completely divided hepatic duct from which the bile literally poured. A figure which the speaker exhibited showed the anatomical relations and how careful one should be in passing the ligature around the cystic artery, especially if the cystic and hepatic ducts were close together and parallel. He quickly freed the cystic duct and ligated it, and removed the gall-bladder. He then freed the two cut ends of the hepatic duct and saw that his point of division was just below the junction of the right and left duct. Fortunately the tissues of the duct were healthy and it was not very difficult to approximate the two ends. This he did with interrupted sutures of fine catgut, which he passed through the entire thickness of the duct. He made a complete circular suture and reinforced it anteriorly with a second row of sutures, and laid omental tissue over it. A cigarette drain was placed lateral to the line of suture and a gauze tampon was laid in the bed of the gall-bladder. The wound was closed in the usual fashion. The convalescence was relatively uneventful. The biliary drainage gradually decreased and upon the day of the patient's discharge, twenty-six days after the operation, had practically ceased. The patient felt perfectly well and had gained thirty-four pounds since her operation.

Dr. V. GAUDIANI pointed out that the work of Ruge, Rio Branco and others had recently illustrated certain points regarding the anatomy of the biliary tracts, especially as regarded the anomalies of the cystic duct and cystic artery. From the new researches, following practical hints which made impossible mistakes in the technique, as referred to by Dr. Stettin, he offered the following: (1) One should ligate separately the cystic duct and cystic artery; then one did not risk taking together the hepatic or common duct which formed the left side boundary of the Callot's triangle; (2) the ligation of the cystic artery should be made near the neck of the gall-bladder where usually it divided in two branches. Even in an anomalous condition it was almost impossible to ligate the hepatic artery or its branch to the right lobe because of the well-known fatal consequences.

Epithelioma of the Nose Treated by Radium.—Dr. ISAAC LEVIN reported this case, which was cured by the application of radium for a period of six hours. Though the tube was larger than the ulcerated surface the adjacent surface of the skin was not in any way injured by the radium.

Primary Cancer of the Vagina Treated by Radium and the Röntgen Rays.—Dr. LEVIN reported this case, which he said had been declared inoperable. A diagnosis was made of primary carcinoma of the vagina. Microscopical examination showed a squamous celled epithelioma. After eight weeks of combined radium and röntgen treatment all the clinical symptoms of the disease disappeared. A microscopical examination now showed no evidence of carcinomatous tissue. At the present time, sixteen months after beginning the treatment, the patient felt perfectly well and had gained forty-five pounds.

Carcinoma of the Breast (Bone Metastasis) Treated by Radium and Röntgen Rays.—Dr. LEVIN reported this case, in which, three years after an amputation of the left breast for carcinoma, there developed a swelling (2 x 1 x ¾ inches) adherent to the left clavicle. The radiograph showed partial destruction of the bone and consequently a metastasis in the left clavicle. Under combined radium and röntgen treatment the swelling practically disappeared. At present, nine months after the beginning of treatment, the patient was clinically well and there was no indication of any recurrence.

Rhinoscleroma Treated by Radium: Two Cases.—Dr. LEVIN reported these cases. He stated that the first patient had been suffering with this affection for the past thirteen years and had been operated upon frequently. After operation the disease always promptly recurred. Radium treatment was begun fifteen months ago. She was at present completely cured clinically as well as anatomically, and had been without any symptoms of obstruction for nearly a year.

The Efficiency of the Coolidge X-Ray Tube and the Rationale of Radiotherapy in the Treatment of Malignant Tumors.—Dr. LEVIN presented this paper, in which he first made a comparative study of the efficiency of the Coolidge and the so-called Gauss tube for therapeutic purposes, the results of which he summarized as follows: It took about one-third of the time to obtain the same quantity of rays on the surface with a Coolidge tube as compared with the older type of tubes. At the depth of two inches of meat the strip showed about one-third of the quantity of the rays shown by the surface strip during the same experiment with the old-type tube and about one-half by the Coolidge tube. At the depth of four inches there was usually about one-seventh of the quantity shown on the surface obtained from a Gauss type, while from a Coolidge tube one obtained at the same depth usually one-fifth of the quantity shown on the surface. There was no complete regularity in the results of the experiments with either tube, but the Coolidge tube showed a far greater uniformity. Another great advantage of the Coolidge tube was that when it was regulated to a certain penetration it remained so for an indefinite length of time. The writer then presented a report of forty-one cases of deep-seated malignant tumors treated by him during the last eighteen months with the modern method of radium and Röntgen therapy. Among these cases were carcinoma of the breast, mouth, larynx, esophagus, uterus, vagina, ovary, urinary bladder, stomach, sigmoid and rectum, and four cases of sarcoma. Of these forty-one cases, three were at present clinically cured; several cases not clinically cured showed morphological changes in the tumors which strikingly indicated the value of radiotherapy in the treatment of malignant tumors, when the type of cases, the time, and the method of treatment were correctly selected. A statistical analysis of 1002 cases obtained from the literature on the subject of radiotherapy of malignant tumors showed that 6.6 per cent. of inoperable deep-seated malignant tumors might be clinically cured by radiotherapy. This was a better result than had ever been offered by any therapeutic measure, but it did not indicate the true value of this method of treatment, since it had been shown that minute metastatic nodules could be destroyed by the aid of radiotherapy at a great distance from the surface of the body. Dr. Levin presented specimens of carcinoma of the sigmoid which had been treated by the Röntgen rays. He related the history of the patient from whom the specimen had been removed and described the post-mortem findings, from which he deduced the following points: Notwithstanding the continuous, very large doses of Röntgen rays there was no injury to the skin, serous or mucous membranes, lymphatic glands, or parenchymatous organs. At the same time the islands of tumor cells in the peritoneal nodules were either completely destroyed and replaced by dense fibrous connective tissue or surrounded by the connective tissue and inhibited greatly in their growth. In over six months not a single one of the innumerable minute nodules found at the operation developed into a large metastasis. The original sigmoid tumor did not increase in size during this time. It was thus self-evident that the rays exerted a specific deleterious effect on carcinoma cells when used in such a quantity as would leave the remainder of the organism intact. On the other hand, the tumor must not exceed a cerain size in order to be influenced effectively by the rays. This case also illustrated the importance of combined surgical treatment and radiotherapy of malignant tumors. The gross tumor should be removed surgically even when a radical operation could not be performed, then the small islands of cancerous tissue might be destroyed by raying even at a distance. This case also suggested the importance of prophylactic post-operative treatment. Such prophylactic treatment might fail in those cases in which there existed at the time of the operation large secondary metastatic tumors.

The Anatomy of the Superficial Fascia of the Groin in Relation to the Operation for Undescended Testicle, and an Explanation of the Ectopic Testicle of the So-called Perineal Type.—Dr. C. G. BURDICK read this paper. He stated that having made the mistake, and seen others make a similar error, of not replacing the testicle in the scrotum in operations for undescended testicle, he had been led to make several dissections of the superficial fascia of the inguinal region, with the following results: The deep layer of the superficial fascia as it passed downward over the inner aspect of Poupart's ligament divided, the anterior layer passing downward in front of the spermatic cord to become continuous with the dartos of the anterior portion of the scrotum, the posterior passing behind the cord formed a free edge which lay 1 to 2 cm. below the pubic spine and was attached to the symphysis pubis. Therefore the cord entered the scrotum between these two fascial planes. If an instrument such as a pair of blunt scissors was passed between this free edge one could readily demonstrate how this posterior layer extended downward and inward, and was attached to the margin of the ramus of the pubis and ischium internally and below, and externally to the fascia lata. The importance of this posterior layer of fascia in attempting to replace an undescended testicle in the scrotum lay in the comparative ease with which a testicle might be replaced beneath it and so by no possible chance could it ever get into the scrotum. These two fascial planes were readily demonstrated in every operation for an undescended testicle by placing a blunt retractor in the lower angle of the wound and by retracting the skin upward and inward the two planes would be readily brought into view. The finger was now passed beneath the posterior plane and it entered the thigh, but by making a little effort, and here was where one was likely to be led astray, provided this layer was sufficiently lax, the finger apparently entered the upper part of the scrotum. This in a case of undeveloped scrotum quite possibly might lead the operator to think he was in the right plane, and that by forcing his finger down a little further it would be in the right place, but of course this was impossible anatomically. Now if the finger was withdrawn and inserted between the two fascial planes it passed directly to the bottom of the scrotum. Frequently in operating on these patients the gubernaculum was found passing beneath the posterior layer of the fascia, and, if in following it down with the finger it apparently led into the upper part of the scrotum, one was again misled into thinking he had selected the right path. If the testicle itself lay beneath this plane it usually was considered an ectopic testicle of the perineal type, and, personally, he believed that nearly all, if not all, cases of perineal ectopic were of this variety for the following reasons: (1) It was impossible for a testicle following this route to get into the perineum, as both the above layers and Colles' fascia were attached to the inner margin of the ramus. (2) A testicle which had descended to the bottom of this pouch, thus lying close to the inner margin of the ramus, would easily give the appearance of being in the perineum. (3) The only opening of Colles' fascia was close to the symphysis, at the root of the penis, and he had not been able to find any reported cases in which the testicle had reached the perineum by this route. Dr. Burdick exhibited figures illustrating his text. One figure showed a case upon which he had recently operated in which the vas and its vessels passed between the two fascial planes into the scrotum while the gubernaculum and cremaster still remained, passing beneath the posterior fascial layer and entering the thigh. The speaker said it had been his misfortune in two or three cases of congenital hernia, in which, while operating, the testicle had been brought out of the scrotum and apparently replaced, to find later that the testicle lay outside the scrotum. He had not had the opportunity to reopen any of these cases, but was quite certain that they had been caught under this same layer of fascia and hoped soon to have the opportunity of proving the correctness of this assumption.

Blue Tattooing of Skin from Hypodermic Injections of Morphine.—F. Parkes Weber reports a case of this condition in a woman aged 67 years, a morphinist, who from the age of 27 to the age of 59 had been accustomed to take morphine, almost entirely by the mouth, up to 8½ grains a day. She then entirely discontinued taking the drug until after an operation for gall-stones, about four years ago, when she got into the habit of giving herself hypodermic injections of morphine and atropine. Since then she had usually, in the course of every day (twenty-four hours), injected from 1 2/3 to 3 1/3 grains of morphine sulphate, together with from 1/24 to 1/10 grains of atropine sulphate under the skin of her upper extremities or the upper part of the front of her chest. At the time of the report the skin of these regions had a stippled appearance from innumerable minute bluish spots, each bluish spot marking the site of a former hypodermic injection.—*Proceedings of the Royal Society of Medicine.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

MISSISSIPPI STATE BOARD OF MEDICAL EXAMINERS.

Jackson, May 11, 1915.

ANATOMY.

1. Describe external iliac artery. Give relations. Name branches.
2. Trace the blood from the big toe to the retina of the eye.
3. Give origin, insertion, and function of deltoid muscle.
4. Describe sciatic nerve. Give divisions of same. Name muscles supplied.
5. Describe hip-joint. Give kind of articulation. Name ligaments of same.
6. Describe fifth cranial nerve. Give its distribution and function.
7. Describe portal system.
8. Describe external carotid artery. Give relations. Name branches.

PHYSIOLOGY.

1. Name the cranial nerves that are exclusively motor in function, and describe any one of them.
2. Describe in detail the pneumogastric nerve.
3. Name and give function of the digestive secretions naming the active agents in each.
4. Describe the heart sound, and give causes for the sounds.
5. Define blood pressure, and give method for determining it.
6. Locate the respiratory center.
7. Name the secretions and excretions.
8. Name six abnormal constituents of urine.

CHEMISTRY.

1. Name four elements that are gases and give symbol for each.
2. What is the molecular weight of water?
3. Give the chemical formula for each of the following: (*a*) Ammonia. (*b*) Ferric chloride. (*c*) Hydrocyanic acid. (*d*) Laughing gas. (*e*) Ethyl alcohol. (*f*) Benzene.
4. Complete the following equations: $HNO_3 + KOH$ equals.
5. Write equation showing how slaked lime is formed.
6. What elements are the most common constituents of organic compounds?
7. What is the simplest saturated hydrocarbon and its graphical formula?
8. What is Fehling's solution and its use?

MATERIA MEDICA.

1. Give habitat, common name, and one official preparation with dose of (*a*) digitalis; (*b*) gelsemium; (*c*) belladonna; (*d*) aspidium; (*e*) physostigma; (*f*) colocynth; (*g*) veratrum viride.
2. Name two commonly used derivatives of morphine and give dose of each.
3. Name the ingredients of (*a*) Dover's powder; (*b*) Seidlitz powder; (*c*) black wash; (*d*) Carron oil; (*e*) Fowler's solution.
4. Why are the salts of the alkaloids generally used instead of the alkaloids themselves? (*b*) Name and give dose of five alkaloidal sulphates.
5. Mention ten drugs, any one of which when taken internally may produce skin eruption.
6. Give the best chemical antidote for (*a*) arsenous acid; (*b*) bichloride of mercury; (*c*) iodine; (*d*) phosphorus; (*e*) all alkaloids.
7. By what rule would you determine the dose of any medicine for a child?
8. How much of any drug is contained in one ounce of a 5 per cent. solution of such drug.

HYGIENE.

1. Describe a sanitary school building.
2. How would you manage an epidemic of typhoid fever in a town of three hundred or more?
3. In what way do the germs of disease enter our bodies? Describe the five most important.
4. Give hygienic management of a case of tuberculosis in a home.
5. What diseases are transmitted through human excreta?
6. What diseases may be transmitted through milk? What precautions should be taken to prevent these?
7. Discuss briefly the hygiene of infant feeding.
8. What is soil pollution? How is hookworm disease contracted?

OBSTETRICS.

1. Give diagnosis and treatment of extra-uterine pregnancy after rupture.
2. Give cause and treatment of mastitis.
3. Give symptoms, diagnosis and treatment of placenta prævia.
4. What are the uses of the liquor amnii during pregnancy? During labor?
5. How would you deliver a child, when face is presenting with chin posterior?
6. To prevent laceration of the perineum, describe the proper method of delivery of the head.
7. Give treatment of pregnancy complicated with nephritis.
8. Give treatment of pernicious vomiting of pregnancy.

PATHOLOGY.

1. Describe the difference between an embolus and thrombus, and where do you most frequently find an embolus?
2. Explain what is meant by the terms physiologic and pathologic leucocytosis? State whether leucocytosis occurs in the following diseases: typhoid fever, malarial fever, pneumonia, acute miliary tuberculosis.
3. By what methods would you make a diagnosis of tubercular lesions?
4. What general pathological condition characterizes chronic alcoholism?
5. What pathological conditions do we find in the different stages of lobar pneumonia?
6. Give the gross pathology of amebic dysentery. Describe the organism giving rise to it, and give pathological condition of the liver associated with it.
7. What abnormal products do you find in diabetes mellitus? In chronic parenchymatous nephritis?
8. Name and explain the cardinal symptoms of inflammation. State the terminations of inflammation.

SURGERY.

1. Define inflammation and give symptoms.
2. Differentiate between septicemia and pyemia.
3. Give varieties of talipes and give treatment for one variety.
4. Give advice on a case of appendicitis, initial attack; you are called in on the third day.
5. In closing a wound give two cardinal principles that must be observed to get union by first intention.
6. Give symptoms and treatment for dislocation of inferior maxilla.
7. Name the signs of a fracture.
8. Name the coverings that would be cut in operating for an oblique inguinal hernia.

ANSWERS

ANATOMY.

1. The *external iliac artery* arises at the point of bifurcation of the common iliac artery, and runs along the brim of the true pelvis to Poupart's ligament, where it enters the thigh as the femoral artery. *In front* of it are the intestines, peritoneum, iliac fascia, spermatic vessels, genital branch of genitocrural nerve, and deep circumflex iliac vein; *behind it* are the external iliac vein (on the right side), and the psoas magnus muscle; on the *outer side* are the psoas magnus and the iliac fascia; and on the *inner side* is the external iliac vein. Further, on the right side the ureter frequently crosses the upper part of the artery. *Branches:* The deep epigastric and deep circumflex iliac.

2. *From the big toe to the retina of the eye* the *blood* will pass through the following veins: Dorsal digital, internal saphenous (or plantar digital, plantar metatarsal, anterior tibial, popliteal), femoral, external iliac, common iliac, inferior vena cava, to right auricle of heart; then to right ventricle, through pulmonary artery, pulmonary veins, to left auricle and left ventricle, and through the following arteries: aorta, common carotid, internal carotid, ophthalmic, and arteria centralis retinæ.

3. DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion

process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus. *Action:* It raises the arm from the side so as to bring it at right angles with the body; its anterior fibers draw the arm forward; its posterior fibers draw the arm backward.

4. *The great sciatic nerve* arises from the sacral plexus and passes out of the pelvis through the great sacrosciatic foramen, below the pyriformis muscle; it extends down the back of the thigh, passing between the great trochanter of the femur and the tuberosity of the ischium; at the lower third of the thigh it divides into the internal and external popliteal nerves. It supplies the hip-joint and the biceps, semitendinosus, semimembranosus, and adductor magnus *muscles*.

5. The *hip-joint* is an enarthrodial joint, formed by the head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the ligamentum teres. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The ileofemoral or Y ligament, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ileum, and below to the anterior intertrochanteric line. (3) The ligamentum teres. (4) The cotyloid ligament, which deepens the acetabulum, and bridges over the cotyloid notch, being there called (5) the transverse ligament. The joint has a very extensive synovial membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction, and rotation.

Fifth Cranial Nerve. *Origin:* (1) *Superficial*, from the side of the pons Varolii; (2) *Deep* (sensory root), from the medulla, and upper part of cord; (motor root) from floor of fourth ventricle, and side of the aqueduct of Sylvius.

Distribution: First or ophthalmic branch supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal glands, mucous membrane of nose. *Second, or superior maxillary branch*, supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch*, supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (masseter, temporal, external pterygoid, internal pterygoid), also to mylohyoid and anterior belly of digastric.

7. *The portal system.* The veins of the portal system collect the blood from the digestive tract. They form a trunk, the *vena portæ*, which enters the liver and breaks up into small branches in its substance. The following veins form the portal system:

Inferior mesenteric: drains rectum, sigmoid, flexure, and descending colon. It lies to the left of its artery, and passing behind transverse part of the duodenum and the pancreas, and over left kidney, opens into the splenic vein. (The hemorrhoidal branches inosculate with the hemorrhoidal branches of the internal iliac.)

Superior mesenteric: drains small intestines, cecum, ascending and descending colon. It passes upwards in front and to right of superior mesenteric artery, in front of transverse part of duodenum, and behind neck of pancreas joins the splenic vein at the upper border of the pancreas to form the portal vein.

Splenic: commences in five or six branches in hilum of spleen; these unite to form a trunk which passes below splenic artery behind upper border of pancreas from left to right, and in front of aorta; joins superior mesenteric at a right angle.

The gastric or coronary: a large vein accompanying coronary artery from right to left along lesser curvature of stomach to cardia, where it reaches esophageal tributaries, and, passing to right behind lesser sac, opens into the vena portæ.—(*Aids to Anatomy.*)

The *portal vein* is formed by the union of the splenic and superior mesenteric veins in front of the right crus of diaphragm and inferior vena cava, and behind the neck of the pancreas. Passes up behind first part of duodenum and then between the layers of the small omentum, behind and between the common bile-duct and hepatic artery, the duct being placed on the right and artery on the left, to transverse fissure of liver, where it divides into right and left branches to corresponding lobes, and also gives an offset to the Spigelian lobe. Connected with the branch to the left lobe are in front the *obliterated umbilical vein* and behind the *ductus venosus*, the remains of a fetal connection with the inferior vena cava.—(*Aids to Anatomy.*)

8. The *external carotid artery* arises at the point of bifurcation of the common carotid artery, opposite the upper border of the thyroid cartilage, passes upwards and ends in the substance of the parotid gland behind the neck of the lower jaw, where it divides into the superficial temporal and internal maxillary arteries. *Relations: In front*, skin, fascia, platysma, sternomastoid, lingual and facial veins, digastric, stylohyoid, hypoglossal nerve, and parotid gland; *behind*, superior laryngeal nerve, styloglossus, stylopharyngeus, glossopharyngeal nerve, and parotid gland; *externally*, the internal carotid artery; *internally*, hyoid bone, pharnyx, superior laryngeal nerve, parotid gland.

The branches of the external carotid artery are: Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.

PHYSIOLOGY.

1. *Cranial nerves that are exclusively motor in function:* Motor oculi, trochlear, abducens, facial, spinal accessory, and hypoglossal.

The *third cranial nerve* (motor oculi) arises from the inner side of the crus cerebri, in front of the pons, and from the floor of the aqueduct of Sylvius. It enters the cavernous sinus and then passes forward to enter the orbit through the sphenoidal fissure. While in the sphenoidal fissure it divides into two branches. It is the motor nerve for the muscles of the eyeball, and is distributed to all of these muscles except two. It supplies the superior rectus, levator palpebræ superioris, internal rectus, inferior rectus, and inferior oblique muscles.

2. *Pneumogastric nerve. Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Course:* Outward across the flocculus, to jugular foramen through which it passes; here it is joined by the accessory portion of the spinal accessory nerve. As it goes down the neck, it lies in front of the *rectus capitus anticus* major and longus colli muscles. It passes in the carotid sheath behind and between the artery and vein. In the thorax the nerve on each side runs a different course. The *right* passes between the subclavian artery and vein, by side of trachea to root of lung, behind esophagus, through esophageal opening in diaphragm to posterior surface of stomach. The *left* passes between the subclavian and carotid arteries, in front of arch of aorta to root of lung, along anterior surface of esophagus, through diaphragm, to anterior surface of stomach. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric. *Function:* It supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc.

3. The secretions of the alimentary canal are: Saliva, gastric juice, pancreatic juice, bile, and succus entericus. Of these the gastric juice has an acid reaction; the others, alkaline.

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) to change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so

promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and erepsin, which assist the pancreatic juice in digestion.

SECRETIONS.	ACTIVE PRINCIPLES.	FUNCTIONS.
Salivary	Ptyalin.	Changes starches into dextrin and sugar.
Gastric	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal	Invertin.	Converts maltose into glucose.

4. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause.. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

5. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure is estimated by a syhygmomanometer.

"The individual whose blood pressure is about to be recorded should be placed in such a position that his heart, the artery the blood pressure of which is to be determined, and the manometer are at the same level. It is usual to record the pressure in the brachial artery. The india-rubber bag of the instrument should be wrapped round the bared arm, the metal covering of the bag should then be adjusted, and firmly strapped in position. The india-rubber tube leading from the bag is then adjusted to the proximal limb of the U-shaped manometer which contains mercury. The experimenter places the index finger of his left hand over the radial pulse of the subject, and with his right hand he compresses the syringe and so drives air into the india-rubber tube and the india-rubber bag around the individual's arm. The pressure of the air in the bag around the arm is recorded by movement of the mercury from the proximal to the distal limb of the manometer. The operator keeps on pressing the syringe until oscillatory movements are seen at the surface of the mercury in the distal limb of the manometer; the mean point of maximum oscillations registers the diastolic pressure. If the pressure in the bag is still further increased, the oscillations diminish in amplitude and finally disappear, and at this point the pulse can no longer be felt at the wrist. The height of the mercury supported then registers the amount of systolic pressure. It will then be noted that the mercury has descended in the proximal limb of the manometer, and has ascended in the distal limb of the manometer: the difference between the two mercurial levels will be the blood pressure of the brachial artery. The normal systolic pressure in man is about 120 mm. Hg, and the diastolic pressure about 100 mm. Hg. In women the pressures are about 10 per cent. less. In children the systolic pressure may be as low as 90 mm. Hg, with a diastolic pressure of about 80 mm. Hg. (R. Hutchison.)

6. The respiratory center is situated in the lowest part of the floor of the fourth ventricle at the calamus scriptorius.

7. *Secretions:* Sebum, mucus, serous fluid, tears, saliva, gastric juice, succus entericus, pancreatic juice, bile, milk, sweat, urine, seminal fluid, and the various internal secretions.

Excretions: Urine, carbon dioxide, sweat.

8. *Six abnormal constituents of urine:* Albumin, sugar, blood, pus, bile, and indican (in excess).

CHEMISTRY.

1. *Four elements that are gases:* Hydrogen, H; oxygen, O; chlorine, Cl; nitrogen, N.

2. *The molecular weight of water:* H = 1, O = 16; $H_2O = 18$.

3. Ammonia, NH_3; Ferric chloride, Fe_2Cl_6; Hydrocyanic acid, HCN; Laughing gas, N_2O; Ethyl alcohol, C_2H_5OH; Benzene, C_6H_6.

4. $HNO_3 + KOH = KNO_3 + H_2O$.

5. $CaO + H_2O = Ca_2H_2O_2$.

6. Carbon, hydrogen, oxygen, nitrogen.

7. The simplest saturated hydrocarbon is methane, CH_4.

8. Fehling's solution is a mixture of copper sulphate, caustic soda and potassium tartrate. It is used as a reagent in testing urine for sugar.

MATERIA MEDICA.

1. DIGITALIS. *Habitat,* Europe; *common name,* foxglove; tincture of digitalis, dose 15 minims.

GELSEMIUM. *Habitat,* Southern United States; *common name,* yellow jasmine; tincture of gelsemium, dose 8 minims.

BELLADONNA. *Habitat,* Europe and Asia Minor; *common name,* deadly night shade; tincture of belladonna leaves, dose 8 minims.

ASPIDIUM. *Habitat,* Europe, Northern America and Northern Asia; *common name,* male fern; oleoresin of aspidium, dose 30 grains.

PHYSOSTIGMA. *Habitat,* tropical Western Africa; *common name,* Calabar bean, or ordeal bean; tincture of physostigma, does 15 minims.

COLOCYNTH. *Habitat,* Southern Asia and the countries bordering the Mediterranean Sea; *common name,* bitter apple; extract of colocynth, dose ½ grain.

VERATRUM VIRIDE. *Habitat,* North America; *common name,* hellebore; tincture of veratrum, dose 15 minims.

2. *Two derivatives of morphine: Apomorphine;* emetic dose of apomorphine hydrochloride 1/10 grain. *Heroin,* dose 1/18 grain.

3. *Dover's powder* contains ipecac 10, powdered opium 10, and sugar of milk 80.

Seidlitz powder contains potassium and sodium tartrate 120 grains, sodium bicarbonate 40 grains and tartaric acid 35 grains.

Black wash contains 30 grains of calomel in 10 ounces of lime water.

Carron oil contains equal parts of lime water and linseed oil.

Fowler's solution contains arsenous acid 1, potassium bicarbonate 2, compound tincture of lavender 3, and distilled water to 100.

4. The salts of the alkaloids are, as a rule, soluble in water, whereas the alkaloids are but slightly soluble in water. For this reason the salts are more generally used than the alkaloids themselves.

Five alkaloidal sulphates: Morphine sulphate, dose 1/4 grain; strychnine sulphate, dose 1/64 grain; atropine sulphate, dose 1/160 grain; quinine sulphate, dose 4 grains; codeine sulphate, dose 1/2 grain.

5. *Ten drugs whose internal use may cause a skin eruption:* Bromine and the bromides, iodine and the iodides, cubebs, copaiba, salicylic acid, quinine, turpentine, antipyrin, belladonna, chloral.

6. *Chemical antidote* for *arsenous acid,* freshly prepared solution of ferric hydroxide; for *bichloride of mercury,* white of egg, or milk; for *iodine,* starch; for

phosphorus, no chemical antidote, but old French oil of turpentine is recommended; for *alkaloids*, tannin.

To determine the proper dosage for a child: Let x = the age of the patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

8. One ounce = 480 grains; a 5 per cent. solution will contain 5/100 or 1/20 of 480 grains = 24 grains.

HYGIENE.

1. A SANITARY SCHOOL BUILDING. "The *site* of a school building must be well drained, either by nature or artificially; it must be convenient of access; it should not be near enough to railroads or noisy factories to allow the noise to interfere with work; it should have ample playground space; it should have some shade; the surface should be graveled or turfed; walks must connect the school house with the street or road and with outhouses and water supply. The *foundation* must be impervious to soil-water in order that capillarity may not dampen the walls. They should be of non-porous natural stone, hard-burned brick or concrete, and if of concrete must have a layer of tarred felt, tarred paper or impervious stone or brick interposed between the foundation and the superstructure. If there is a *basement* it should rise sufficiently high above the ground for light and air to penetrate to every part of it, and should never be allowed to become a dump for refuse of any kind. If no basement is provided, the foundation walls should be pierced in appropriate places and guarded with gratings, in order to allow a circulation of air below the floors. *Cloak-rooms* must always be provided in order to avoid the stuffy and disagreeable odor of clothing in damp weather. In the country, shelves for dinner pails should also be provided. *Toilets* must be separate for the sexes, well screened, well painted or whitewashed, and kept clean. If water-closets are used, a type should be selected which can easily be scrubbed, and an automatic flush is desirable. Urinals must be placed in the toilets allotted to boys. *Wash-rooms.*—Children should be afforded an opportunity for cleansing the hands and face after play or visits to the toilet. For this, if piped water is available, the ordinary porcelain basins with run-off to the sewer connection should be installed. In case it is not available, ordinary granite or enameled basins, with a water supply in buckets or tanks should be possible to any school. Paper towels or individual towels brought by the children must be used. The use of roller towels is an abomination. *Water Supply.*—A supply of water under pressure is necessary, which will provide not only water for drinking and washing, but for water-closets, the outflow from which can be purified by a septic tank before its final disposal. *Space.*—Not less than 225 cubic feet of space must be allotted to each person in the schoolroom, including the teacher. Twelve-foot ceilings are best for all purposes. *Ventilation.*—Whatever means are used must provide for a complete change of air in 15 to 20 minutes. This is best tested by using the "bee-smoker," which fills the air with light smoke from burning rags, and if the air is completely clear in the time named the ventilation may be regarded as satisfactory. Whatever system of *heating* is employed should maintain the temperature of every part of the school room between 65° and 70° F., with a relative humidity of at least 40 per cent. Should the temperature fall below 60° the school must be dismissed at once. *Humidity.*—Some means, even if only the placing of pans of water on stoves or radiators, must be provided for adding to the moisture in the air. The room should be *lighted* from one side only, or by properly softened sky-lights, and the lighting area should not be less than one-sixth of the floor area. Prismatic glass in the upper sash is an advantage, since it diffuses the light to the opposite side of the room. *Seats* must be adjustable to the bodies of the children. It is nothing short of criminal to compel the child to adjust itself to the seat. Good work cannot be done by an uncomfortable child, and lasting eye-trouble or bodily deformity such as spinal curvature may come from the practice. *Blackboards* should be always dull-finished. A glossy blackboard is unnecessarily hard on the eyes. Blackboards and erasers should not be cleaned while school is in session, and erasers should be dusted outside. The chalk racks should be cleaned each evening by the janitor."—(Gardner and Simonds' *Practical Sanitation.*)

2. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

3. *Avenues of entrance for the germs of disease:* Skin and mucous membrane, digestive tract, respiratory tract, genital tract, conjunctiva, placenta.

4. *Hygienic precautions to be taken in treating a case of tuberculosis:* "The patient's quarters should be free from dust, and admit of his spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be unearpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel night-gown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water." (Thompson's *Practical Medicine.*)

5. *Diseases transmitted through human excreta:* Actinomycosis, bubonic plague, chickenpox, cholera, amebic dysentery, bacillary dysentery, typhoid.

Diseases specially liable to be conveyed by the ingestion of milk: Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsillitis, cholera, and gastrointestinal disorders.

The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt, or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

Essentials for the production and preservation of pure dairy milk: Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk

in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60° F."

7. "If the mother cannot nurse her infant, it must be nourished by a wet-nurse. When none can be obtained, give cow's milk one part (by measure) or two parts of water and add milk sugar, 3 iv. to each pint of the mixture, the proportion of milk to be increased with age. When this food disagrees, and the child passes lumps of undigested curd, one-third of the water may be exchanged for lime-water. The water must be sterilized by boiling, and the milk not by boiling, which impairs its nutritive value, but by Pasteurization—*i. e.* by keeping it continuously for thirty minutes at a temperature of 167° F. It is of the utmost importance that nipples, bottles, and vessels in which the food is prepared should be kept aseptically clean. They must not be used twice without being thoroughly cleansed—the bottles and vessels scalded and the nipples immersed in a solution of boric acid. The best rule as to how much of the milk-mixture should be given the child at one time, is to give it as much as it will readily take; if it rejects any, give it less next time." (King's *Manual of Obstetrics.*)

8. Soil pollution consists of the urine and droppings of animals, the carcasses of animals that have died, and vegetable matters in various stages of decay, also sewage and dead bodies.

Prophylaxis of hook-worm disease: Children and adults should be made to wear shoes; proper toilet facilities should be provided, and their use enforced; bathing or wading in shallow water should be forbidden; a proper water supply should be available for drinking purposes; and prompt recognition and treatment of all cases should be encouraged.

OBSTETRICS.

In *extrauterine pregnancy*, there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. The *treatment after rupture* is—laparotomy. "After thorough cleansing and sterilization of the abdomen and pubes, as well as of the instruments and hands of the operator and assistants, the bladder is emptied and the patient anesthetized. An incision 3 inches long is then made in the median line above the pubes down to the peritoneum, any bleeding vessels being twisted before opening the peritoneal cavity. The peritoneum is then incised; the intestine kept back by pads of cotton or gauze wrung out of sterilized water; the operator's fingers bring out the distended tube and ovary at the incision after having freed them from any existing adhesions; the pedicle is then transfixed by a double ligature of sterilized silk, and each half of it tied securely according to surgical rule. The pedicle is cut, and the entire mass—the Fallopian tube, with the cyst, fetus, ovary, and effused blood, removed, extra care being taken, in the ruptured cases, to quickly secure the bleeding vessels of the ruptured tube from further hemorrhage. The pads are then withdrawn and the abdominal incision closed and dressed in the usual manner. In case of threatened collapse from hemorrhage during the operation, the peritoneal cavity may be flooded with a 1 per cent. sterilized solution of common salt at a temperature of 100° F., a quart of this solution having been previously prepared. It is rapidly absorbed by the peritoneum, and acts as a restorative—like transfusion."—(King's *Obstetrics.*)

2. MASTITIS. *Etiology:* Infection, generally due to handling; cracked or sore nipples and overactivity of the gland with retained secretion are predisposing causes. *Treatment:* This consists in resting the part; supporting it, applying a hot boracic acid fermentation; nursing from the affected breast should be stopped at once.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure.

3. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Varieties:* (1) *Central*, when the placenta completely covers the os. (2) *Partial*, when the placenta overlaps the os. (3) *Marginal* or *lateral*, when the placenta reaches the margin of the os but does not overlap it. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Dangers:* Hemorrhage, sepsis, death of the mother, death of the fetus. *Treatment:* stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

4. LIQUOR AMNII. *Functions:* (*a*) *During pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus. (*b*) *During labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

5. "*In mento-posterior positions*, endeavor to secure anterior rotation of the chin when it fails to take place spontaneously. The several methods of attempting this are: 1. Press the forehead backward and upward during a pain, so as to make extension more complete, and thus cause the chin to dip lower down and touch the anterior inclined plane upon which it may glide forward. 2. Put a finger in the mouth, or on the outside of the lower jaw, and draw the chin forward during a pain. 3. Apply the straight forceps and twist the chin to the pubes. 4. Apply the vectis, or one blade of the forceps, under the most posterior cheek, and over the anterior inclined plane, thus, as it were, thickening the latter, so as to make it reach the malar bone and constitute a *point d'appui* which the chin can touch and so glide forward. Should these attempts to secure anterior rotation fail, an effort may be made with the hand, vectis, or fillet, to bring down the occiput and convert the face into a head presentation. In order to succeed in this maneuver the membranes should be unbroken, the os uteri dilated, the face not so deeply engaged that it cannot be lifted to or above the pelvic brim, and an anesthetic administered. Again, failing in this way to produce anterior rotation, the head, if it be not too deeply engaged in the pelvis, and have not passed through the os uteri, may be pushed back, and the child be delivered by podalic version. Should none of these methods be practicable and the head become impacted in the pelvis with the chin toward the sacrum, the only resort is craniotomy. Attempts have been made in these cases to deliver by forceps after lateral incision of the perineum, but they can only succeed when either the child is small or the pelvis over-large. Usually the child's life has been so far imperiled by delay and its consequences that craniotomy may be done without compunction. Possibly symphyseotomy may prove useful in these cases in future. In all cases of face presentation special care is necessary to avoid rupture of the perineum" (King's *Manual of Obstetrics*).

6. *To protect the perineum:* The patient should be restrained from bearing down unduly; extension of the head must be retarded, and the central part of the occiput must be allowed to be born first; pressure must be made with the hand between the coccyx and the anus; when the perineum has had time to stretch, extension and expulsion are allowed; after the birth of the head care must be taken to see that the perineum is not torn by the birth of the shoulders.

7. *Treatment of pregnancy complicated with nephritis:* "Prophylaxis is of the first importance. The urine should be examined every month in the first six months of every pregnancy, no matter how normal it

may seem, and every fortnight in the last three months. If albumin is present, the amount should be estimated in an Esbach tube, and the urea in a Doremus ureometer. The total quantity of urine per diem should also be ascertained. The principles of treatment are to relieve the kidneys by free elimination by the bowels and skin, and by diminishing the nitrogenous part of the dietary; and at the same time to prevent any further interference with the renal functions by guarding against cold. In mild cases where the albuminuria is the sole symptom, the patient should be warned to rest and guard against cold. The diet should be restricted to milk food, with bread and butter, and a little fish or chicken once a day, and the bowels should be made to act freely once every day. Where there are, in addition, symptoms such as edema or headache, the patient should be kept in bed, the diet even more rigidly restricted, and nothing but milk foods given for some days. The bowels should be briskly purged by a hydragogue, such as jalap, and the kidneys flushed out with diluent drinks. This treatment must be continued until the symptoms have disappeared, although it is rare for the urine to clear up altogether. A little fish and chicken, and some light fruits and vegetables may then be added to the diet, but the regular free action of the bowels must be continued. In more severe cases the skin functions must be stimulated in addition by the use of hot packs. The diet also should be nothing but plain milk and diluent drinks. Hot salines per rectum help to flush out both bowels and kidneys. If the condition grows worse in spite of treatment, it argues either a very severe toxemia, or severely damaged kidneys. The outlook in either case is so bad, owing to the probable onset of eclampsia, that the pregnancy should be terminated, particularly as the prospects of obtaining a healthy living child are remote. This interference becomes urgent if signs of drowsiness indicate approaching coma, or sickness and epigastric pain suggest the near onset of eclampsia. The obstetric treatment then consists in emptying the uterus. Where there is no great urgency this should be done by Krause's method of induction of premature labor. In urgent cases some method of *accouchement forcé* must be employed, the choice depending upon the condition of the cervix, and on the degree of urgency" (Johnstone's *Text-book of Midwifery*).

8. *Pernicious vomiting of pregnancy*. "The treatment consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found, it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium oxalate, hyoscine hydrobromide, antipyrine, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed (*Pocket Cyclopedia*).

PATHOLOGY

1. *Thrombus* is a blood-clot formed within the heart or blood vessels during life.

Embolus is a clot or other substance brought by the blood current, and forming an obstruction where it lodges.

Emboli are most frequently found in the following arteries: Pulmonary, renal, splenic, cerebral, iliac, axillary, mesenteric and coronary.

2. A *physiological leucocytosis* is a leucocytosis which is found in certain physiological conditions; it is generally moderate and of brief duration. It is found in the newborn, after parturition, after exertion, after a cold bath or massage, during pregnancy, and during digestion.

A *pathological leucocytosis* is a leucocytosis which is found in certain pathological conditions; it is generally found in inflammatory, toxic, and infectious conditions. As a rule, the polynuclears are increased.

Of the diseases mentioned there is a leucocytosis present in: Pneumonia. It is absent in: Typhoid, malaria, and acute miliary tuberculosis.

3. Tuberculous lesions may be diagnosed by the various tuberculin tests, such as those of Koch, von Pirquet, Calmette, and Moro.

4. In *chronic alcoholism* there may be found peripheral neuritis, meningitis, catarrh of stomach, cirrhosis of liver, arteriosclerosis, and granular kidney.

5. Acute Lobar Pneumonia. "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aërated. The lung still floats in water. *Second stage or red hepatization*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Moderate enlargement of the spleen is very common" (Wheeler and Jack's *Practice of Medicine*).

6. "In *amebic dysentery* the lesions are chiefly seated in the large intestine. They present: (a) Small gelatinous swellings of the mucosa, with partial ulceration; (b) Necrosis and sloughing of the underlying tissues. The ulcers of amebic dysentery thus have undermined edges. The amebæ are found in the ulcerating mucosa, but more abundantly in the tissues beyond the ulcerated area (submucous or muscular coat), where they set up edema and necrosis. Later, along with the ulcers, cicatrices leading sometimes to partial stricture, may be found. Hepatic abscess, usually single, and hepato-pulmonary abscess, are common complications. Amebæ are sometimes found in the portal capillaries. The *ameba* is a rounded cell with a clear outer ectoplasm, and a granular endoplasm. It has a rounded or oval eccentric nucleus, and measures from 10 to 15 μ in diameter. On the warm stage it shows active ameboid movement. In the resting stage it forms a cyst or cysts, and in this state resists drying for a long time. The organisms are found chiefly in the large intestine, especially in the rectum and flexures, but they also occur in the ileum and stomach, and in the liver. They have the power of penetrating the tissues" (Wheeler and Jack's *Practice of Medicine*).

7. In *diabetes mellitus*, sugar is found in the urine; in *chronic parenchymatous nephritis*, the urine will contain granular and hyaline casts and varying amounts of albumin.

8. "Since the days of Celsus, heat, redness, swelling, and pain have been recognized as *cardinal signs of inflammation*, and to these may be added, interference with function in the inflamed part, and general constitutional disturbance. Variations in these signs and symptoms depend upon the acuteness of the condition, the nature of the causative organism and of the tissue attacked, the situation of the part in relation to the surface, and other factors.

"The *heat* of the inflamed part is to be attributed to the increased quantity of blood present in it, and the more superficial the affected area the more readily is the local increase of temperature detected by the hand. *Redness*, similarly, is due to the increased afflux of blood to the inflamed part. The shade of color varies with the stage of the inflammation being lighter and brighter in the early, hyperemic stages, and darker and duskier when the blood flow is slowed or when stasis has occurred and the oxygenation of the blood is defective. In the thrombotic stage the part may assume a purplish hue.

"The *swelling* is partly due to the increased amount of blood in the affected part and to the accumulation of leucocytes and proliferated tissue cells, but chiefly to the exudate in the connective tissue—inflammatory edema. *Pain* is a symptom seldom absent in inflammation. *Tenderness*—that is, pain elicited on pressure—is

one of the most valuable diagnostic signs we possess, and is often present before pain is experienced by the patient. That the area of tenderness corresponds to the area of inflammation, is almost an axiom of surgery. Pain and tenderness are due to the irritation of nerve filaments of the part, rendered all the more sensitive by the abnormal conditions of their blood supply. In inflammatory conditions of internal organs, for example, the abdominal viscera, the pain is frequently referred to other parts, usually to an area supplied by branches of the same nerve as that supplying the inflamed part" (Thomson and Miles's *Manual of Surgery*).

The *terminations of inflammation* are: (1) Return of the tissues to health (by resolution, by organization, or by new growth); and (2) death of tissue, or necrosis (by suppuration, by ulceration, or by gangrene).

SURGERY.

1. *Inflammation* is the succession of changes occurring in a living tissue as the result of some kind of injury, provided that this injury be insufficient immediately to destroy its vitality. *Symptoms of inflammation* are: Redness, swelling, pain, heat, and disordered function.

2. *Septicemia* is a condition due to microorganisms multiplying in the blood, and is characterized by high temperature, but not relieved by getting rid of the original source of infection. *Pyemia* is due to particles of blood clot carrying microorganisms to parts distant from the original source and there setting up metastatic abscesses.

3. *Varieties of talipes: Talipes equinus* consists in extension of the foot, with spasm or shortening of the Achilles tendon, and usually with a loss of power in the anterior tibial group. *Talipes varus* is an inversion of the foot, associated with rotation at the midtarsal joint. *Talipes calcaneus* is characterized by elongation of the tendo Achillis and of the muscles associated therewith, by shortening of the anterior tibial group of muscles, and by slight flexion of the toes. *Talipes valgus* is a deformity of the foot in which eversion is a prominent feature. *Talipes cavus* results from bony subluxation at the midtarsal joint and contraction of the plantar fascia, and produces an exaggeration of the normal transverse arch of the foot.

Talipes equinovarus is a deformity in which the heel is drawn up, and the anterior part of the foot is inverted and drawn inwards.

Treatment: "It may be treated in the early stages by fixing the foot in good position by a series of plaster-of-Paris casings, or by using a malleable metal splint. Tenotomy of tendons which hinder reduction in some cases is necessary, with the subsequent application of plasters. If the ligaments on the inner side of the ankle hinder reduction, they should be divided. In the neglected cases, where the patient has been walking on the outer side of the foot, tarsectomy is necessary. A wedge of bone, with its base outwards, is removed by a chisel or saw, irrespective of the joints, from the tarsus in front of the peroneal groove on the cuboid. The foot can then be brought into good position, and maintained so by plaster-of-Paris" (*Aids to Surgery*).

4. *Treatment of acute appendicitis:* The patient should be kept in bed; no food is to be given for the first twenty-four hours; after this, fluid and jellies may be given; cooling drinks may be allowed in moderation; the pain can be relieved by hot or cold applications on the right iliac region, or morphine may be given if necessary (and only after the diagnosis has been made); an enema of olive oil or glycerine may be given to empty the bowels (if loaded).

The indications for operation vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so, or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack.

5. Stop the bleeding, remove foreign matter, make it as aseptic as possible, coapt the edges, keep the part at rest.

6. In *dislocation of the lower jaw*, the mouth is open and cannot be closed, the jaw protrudes, saliva dribbles from the mouth, speech and swallowing are difficult, and there is a depression in front of the ear. *Treatment:* The surgeon wraps his thumb (for protection), then presses downward and backward on the lower molar teeth; as soon as the condyle is loosened the jaw is closed by pushing up the chin. A Barton bandage is applied and worn for about fourteen days.

7. The *general signs and symptoms of fracture* are: History of injury, disability, pain, swelling, deformity, abnormal mobility, and crepitus.

8. *An oblique inguinal hernia is covered by:* Skin, superficial fascia, aponeurosis of external oblique, intercolumnar fascia, cremasteric fascia, infundibuliform fascia, subperitoneal tissue and peritoneum.

Miscellany.

A Pioneer in Prophylaxis.—The subject of our biograph was a physician, a teacher, a man of letters, and an American. Years before anything was known of the relation of bacteria to diseases the subject of our biograph correlated his own keen clinical observations with the experience of others, and pointed the way toward surgical asepsis—one of the great advances in medicine. His masterly essay on the "Contagiousness of Puerperal Fever," wherein he laid down certain rules to prevent transmission of infectious agents, stands to-day among the great literary landmarks in the history of medicine. Though forced to combat, in his own profession, the deepest skepticism and the most marked opposition to his theories, he lived to see his ideas triumph, and his teachings are now followed by obstetricians and surgeons throughout the world. Let us, therefore, join in honoring Oliver Wendell Holmes, physician, teacher, and man of letters.—*Weekly Bulletin* of the New York City Department of Health.

Treatment of a Failing Current Rectifier.—Not infrequently the owner of a galvanic and faradic wall plate finds that it is inert owing to loss of function of the alternating current rectifier usually employed. This is due in most cases to failure to test the current properly. Moisten a strip of blotting paper in potassium iodide solution and place both tips of the galvanic cords in contact with it, then turn on the galvanic current. If the rectifier is functionating properly a brown stain will appear at the positive pole showing free iodine. If no stain appears it shows that the rectifier is not rectifying the current. Examination of the jars may reveal the fact that the solution has evaporated; or it may be that some one has recharged them with sal ammoniac. The proper salt for this purpose is sodium phosphate. If sal ammoniac has been used the metal plates, being incrusted with salts, must be discarded and a new set of metal plates put in, also new solution. It has been found that a light film of oil poured over the top of the solution greatly increases the life of the rectifier, preventing evaporation of the fluid and creeping of salts.

Reduced Blood Pressure in War.—Dr. A. Moutier recently presented a communication to the Paris Academy of Medicine in which he said that the blood pressure in soldiers returning from the front was almost always markedly reduced. It frequently has been found, Dr. Moutier said, that when a soldier has a wound in one of his limbs the tension in that is lower than in the one which is sound. He believed this lowered blood pressure had much to do with producing various complications, such as gaseous gangrene, tetanus, and frozen feet. He expressed the belief that many amputations might be avoided after gunshot wounds of the extremities if more attention were paid to measures capable of raising and maintaining the intra-arterial tension.

THE FLUOROSCOPIC SCREEN AND THE RADIOGRAPHIC PLATE IN THE DIAGNOSIS OF MEDICAL AND SURGICAL LESIONS OF THE ALIMENTARY TRACT.

BY C. WINFIELD PERKINS, M.D.,

NEW YORK.

THERE is probably no subject before the medical world to-day of more importance and practical interest than the utilizing of the Röntgen ray in diagnosis of gastrointestinal diseases. Much attention has been directed of recent years to the detection of the lesions of the stomach, duodenum and intestines, such as cancer, ulcer, adhesions, and various other pathological conditions of the alimentary tract, the original work of this character having received its impetus by Continental observers, as Holzknecht, Haudeck, Schwartz, and Kienbock of Vienna, Rieder and Groedel of Germany, Beclère of Paris, and many others.

The past three years, and especially the past year, have developed an experience among American workers of much value. To such men as Case, Cole, George, Pfahler, Carmen, Hirsch, and many others we owe a large debt of gratitude for their individual observations and original researches in Röntgen diagnosis. The importance of these methods can be judged from the expressed opinions of such men as von Eiselsberg of Vienna and the Mayos of our own country. Von Eiselsberg says: "In spite of the progress made in the diagnosis of the gastrointestinal diseases, among which I place Röntgen examination as first, the choice of the method of operation for gastric ulcer and cancer can be best made at the autopsy *in vivo*, when the abdominal cavity is opened." In a recent communication in *Surgery and Gynecology and Obstetrics*, December 14, W. J. Mayo says: "Cancer of the stomach is the most frequent form of cancer in the human body. In at least 75 per cent. of gastric cancer the pyloric half of the stomach is involved. The opportunities are many, but the surgeons performing the operation are few and results are meager. Perhaps the most important reason for this apathetic condition of the profession in regard to cancer of the stomach has been our inability to diagnose the disease sufficiently early for the performance of a radical operation with a reasonable operative mortality. At present largely through radiography, the clinical diagnosis of cancer of the stomach can be made early in a large percentage of cases. Exploratory incisions, which up to within the past year were necessary and our chief reliance, though carrying the dread to the patient of an unnecessary operation are fortunately no longer required. The history of the patient, the radiographic findings, the use of the stomach tube, give a reasonable prospect of a correct diagnosis."

Superior technical methods have been developed and new radiological signs have been found. Two schools of radiographic workers have been developed, namely, the Continental school, which is essentially fluoroscopic, and the American school which may be called the Static School. Diverging opinions have, therefore, arisen regarding the method or methods employed to reach a diagnosis. There is no room for this useless controversy over the two methods for signs of gastric and intestinal lesions can be recognized by the screen or the plate alone. Serial plates will demonstrate an involvement, sometimes too small to be found on the screen. One method supplements the other and the skilful use of the screen removes the necessity of many plates and the much laborious and expensive work of the Röntgen laboratory. Combining the screen with the plate, this much-needed diagnostic method can be brought within the reach of all persons and circumstances.

A discussion of the various methods of technique would be superfluous in this paper, but for those who may not know I will outline a few of the methods that are employed by me and which largely follow the Continental technique and that of the Mayo Clinic in Rochester. If the patient's bowels move normally, I cannot see the advisability of giving a laxative and thus disturbing the motility of the intestines; however, if there is no movement, a mild laxative is advised the night before. The patient reports without breakfast and an oatmeal gruel meal is given, 10 ounces with 2 ounces bismuth subcarbonate mixed thoroughly; sugar and milk may be added to make the mixture more palatable. The patient is directed to abstain from further food until he is examined six hours later. His clothing is now removed down to the hips, the screen is placed against the abdomen, and the presence or absence of residue is noted in the stomach. The advanced position of the bismuth meal should be normally in the cecum and ascending colon in six hours. A further advance in the large intestine or retardation in the small intestine is indicative of some pathological process. The patient now drinks rapidly 2 ounces of bismuth, well stirred, in 6 to 8 ounces of water. The entrance of this solution at the cardiac orifice and its descent into the stomach are carefully watched. Any irritation or constrictive lesion being noted, the patency and activity of the pylorus are also observed. The observer palpates towards the pylorus, the outline of the stomach and the visibility of the duodenum being made more pronounced by this procedure. Sixteen ounces of potato-starch pap containing 2 ounces of bismuth or barium salts flavored with some syrup is now

given the patient. This mixture usually fills the stomach so that its outlines are well observed, and any irregularities in the peristaltic wave or defects are noted. Palpation, both in the vertical as well as in the horizontal position, can be done at this

FIG. 1—Typical peristaltic rhythm of the stomach. (Front Groedel, "Die Magenbewegungen.)

time; this is a very necessary part of the technique. Clinical diagnosis offers few parallels to the certainty afforded by this method. If necessary, plates are made with the patient lying down or standing, the abdomen being placed against the plate holder. I think it always advisable to make a large plate of the whole abdomen, intestines, and stomach. Smaller plates may be taken of any special region according to the necessity of the diagnosis required.

After the observer becomes familiar with his technique and has followed a large mass of material, he will find that prolonged examinations are unnecessary with the screen. Screening can be done very satisfactorily in a short time. If there are any signs of gastric or intestinal lesions, they appear at once or do not appear at all. The summing up of the clinical history and the results of the radiological examination will soon lead to something definite or to nothing at all. Errors are more often due to seeing too much from a prolonged examination and the little things are enlarged at the expense of the greater ones.

A Röntgen diagnosis of gastrointestinal lesions is always based on departures from the normal form, tone, position, mobility, capacity, motility, outline, and peristalsis along with phenomena, such as filling defects, spasmodic contractures, accessory pouches, and diverticula of the various parts of the alimentary tube. It is absolutely essential to the Röntgen diagnostician to have a clear, well-defined knowledge of the normal as well as the pathological anatomy of the parts to be examined, in other words, he must not only be an expert clinician but an anatomist and a pathologist of no mean ability.

After the examination of the stomach and the small intestines, subsequent examinations are made at intervals of 24, 36, and 48 hours for the purpose of watching the bismuth meal in various stages of digestion. Stasis, adhesions, motility displacements are all noted in the final summing up of the case. The condition of the appendix as regards its emptying power is also taken into consideration, as an old diseased appendix empties very slowly. It is always advantageous to examine the intestines while the patient lies down, for the palpation of the various portions of the gut can be done more successfully in the recumbent position. Plates may also be taken of the intestines following a fluoroscopic examination as a matter of record.

The outline of the large intestine can be very successfully seen by means of the bismuth enema. It is necessary to do this while the patient lies recumbent with the tube under the table. Various forms of protective apparatus are made which are satisfactory for this work. The ascent of the bismuth column through the descending, transverse, and ascending colon can be watched accurately and any defects, adhesions, tumors, or displacements noted. When the bismuth column reaches the cecum palpation can be made for noting adhesions, and pressure at that point will show whether the ileocecal valve is competent or not; if the mixture is seen to shoot into the small intestine a diagnosis of ileocecal incompetency can be made.

The Normal Stomach.—With reference to form there are two types of stomach: the steer horn and the fishhook. The steer horn, as the name implies, resembles the horn of a steer, having a broad base and narrowing toward the pylorus. The type is comparatively rare and is usually associated with deep-chested and muscular men and rarely found normally in women. The common type is usually the fishhook, or J-type of stomach. It is found in nearly all women and many men.

Tonus is the ability of the stomach to hold its

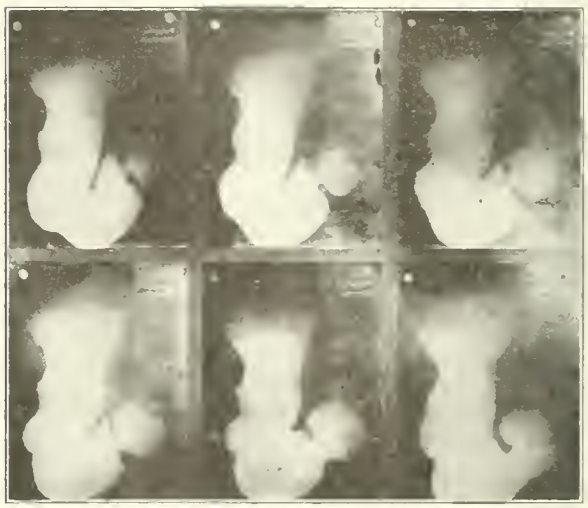

FIG. 2—Phases of the peristaltic waves of the stomach, as visualized with the fluorescent screen

contents firmly. Stomachs are classified by Schlesinger according to tone as hypertonic, orthotonic, hypotonic, and subtonic or atonic. The hypertonic is usually of steer-horn type, orthotonic the fishhook type; the hypotonic is

broad at its base and the bismuth usually settles down, leaving the upper portion relaxed; the atonic or subtonic hangs like a loose bag with the upper walls, the pars media, and cardia collapsed. The position of the stomach always de-

Fig. 3—Schematic drawing after Carman illustrating palpatation with gloved hand behind the fluorescent screen to determine the presence of adhesions or tumors, spasmodic or organic hour-glass contraction.

pends on its form and tone. The steer horn is very high and oblique and the greater curvature is usually placed from 2 to 4 inches above the intercristal line. In the fishhook, J, or orthotonic stomach the greater curvature usually lies on about the level or slightly above the intercristal line, whereas in the hypotonic or subtonic stomach the greater curvature may be anywhere from 2 to 3 inches below the same line and displaced well down into the pelvis. The normal position of the pylorus is in the median line or anywhere to the right in the region of the second or third lumbar vertebra and is always movable. Frequently as a result of adhesions to intestines and gall-bladder, it is pulled over and fixed. Radiologically speaking the normal stomach averages 9 to 11 inches long and 3 to 4 inches in width.

The motility of the stomach is its power to empty itself. The emptying time depends somewhat on the character of food given. Carbohydrates pass sooner than a protein diet. After many competent observations the world over, the failure of the stomach to empty itself of the bismuth or barium salts in 6 hours is indicative of a pathological process; however, an early emptying time may also be associated with a disease process.

The capacity of the normal stomach ranges from 24 to 30 ounces, and any departure from this is usually abnormal. The fixed points of the stomach are the cardia and the pylorus; other portions should be, if normal, freely movable on palpation under the screen. The gastric outline is smooth and regular, though a slight indenture may be noticed below the cardia due to the spleen and should not be mistaken for a deformity. A deeper depression is also observed at the pyloric antrum. A peristaltic wave usually begins at the pars media and becomes deeper as it advances toward the pylorus; the wave is always more pronounced on the lesser curvature than on the greater; at the pyloric antrum it disappears and the food advances into the first portion of the duodenum, usually outlining the bulbus duodeni. This is called a stomach cycle. This functional process begins over again in a normal stomach in about 15 or 20 seconds. During an examination of this process any abnormal condition in its activity, such as exaggeration, prolongation, interruption, or spasm, can be observed and put down as part of the pathological findings. The advances in radiology of recent years have added an entirely new conception of the anatomy and physiology in relation to the form, position, and action of the gastrointestinal canal.

The radiological signs of cancer may be classified as follows: Filling defects; altered pyloric function; gaping or obstruction of the pylorus; hypermotility or advanced position of the six-hour meal (being placed in the left half of the transverse colon or the descending colon); absence of peristalsis over an involved area of the wall of the stomach; six-hour residue as result of stenosis and obstruction; hypertonic stomach, oblique, and placed high up under the diaphragm, due to involvement and stiffening of the walls; finger-shaped projections in the surrounding tissues; hourglass contraction with central canalization; diminished or absent peristalsis; diminished mobility of the stomach; the forming of a diverticulum in the surrounding tissue as a result of the impairment of the walls due to the medullary growth.

The filling defect is a positive and practically indispensable sign of cancer of the stomach. It is formulated by the tumor mass projecting into the stomach, and when the organ is filled with bismuth the gastric lumen shows a corresponding

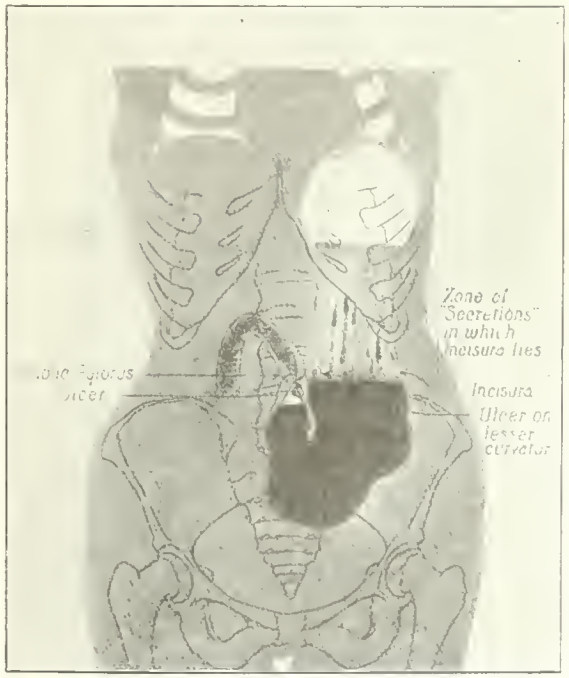

Fig. 4—Schematic drawing after Carman illustrating ulcers of the pylorus and lesser curvature. A large zone of residual secretions is present. Observed under fluorescent screen.

irregularity. These defects vary according to the size and the amount of involvement. There may be various types of defects as a result of the different kinds of tumors; for example medullary carcinoma produces a number of indentations along

the stomach walls, while a scirrhus is apt to be of a small, concentric, narrow, or funnel shape, especially of the pylorus. When the pars media is involved the hourglass type of stomach is formed. Central canalization may result and is diagnostic

Fig. 5—Chronic perforating ulcer (with diverticulum or pouch). Adhesions of the hepatic flexure to the duodenal region. Discovered with the fluorescent screen and verified by the radiographic plate.

of malignancy, while lateral canalization is pathognomonic of a contracture due to an old callus or perforating ulcer. Filling defects must be carefully differentiated from indentations into the wall of the stomach by gas in the colon, adjacent extrinsic tumors, enlarged spleen or liver, mesenteric growths, and organic spasm of the gastric walls. With palpation of the stomach walls while the patient is recumbent, the stomach can be pushed away and indentures filled out, thus showing its true contour. Stomach tumors in contact with the gastric walls are much more difficult to elucidate; under such circumstances the patient may be turned from one position to another and examined at different angles, and the growth's intimate relationship to the stomach may in that way be determined. The deformity due to an organic hourglass contraction is sharply delineated; it is very often irregular in outline and will not relax on palpation or the administration of an antispasmodic such as belladonna or papaverine. In the cardia a filling defect may deform the normal gas bubble or magenblase of the Germans. Examination of the cardiac regions is always more successfully done while the patient is lying down.

The identification of a tumor within or without the stomach or intestines is often a Röntgenological problem. Ordinary clinical examination offers few examples equal to the certainty of a diagnosis afforded by the ability to move the viscera, indent them, and locate pain points and adhesions within a flaccid abdomen, all the while the shadow is visible on the screen. *I again assert that such problems of diagnosis are impossible of solution by any other method.* Altered pyloric function, such as free and continuous passage of food or marked obstruction, is frequently associated with gastric carcinoma. In the pyloric carcinoma, whether from actual stiffening of the antrum or by reason of the lessened acidity of the gastric outlet, it remains gaping and the food shoots out like water in a funnel, while on the other hand a residue may result from obstruction. It is also not infrequent to have hypermotility and a residue as associated findings. These symptoms may seem paradoxical, but they are perfectly logical in the light of reason.

Obstruction may be located at any portion of the gastric lumen, the pars cardia, media, or pylorica. An hourglass stomach frequently shows a residue in its upper sack. A high obstructive lesion very often tends to dilatation of the lower portion of the esophagus. If there is no obstructive lesion in the stomach the head of the six-hour meal may occupy a position more or less proportionate to the acidity; that is, in any portion of the colon from the cecum to the sigmoid depending on the motility. Normally it should be at the cecum and ascending colon, and if anything has passed the left half of the transverse colon, it is pathological. Catharsis must be considered in summing up the diagnosis; some authorities fail to consider this important point. This phenomenon is claimed as a result of hypoacidity of the stomach contents causing immediate evacuation, but there is good reason to believe this interesting symptom may be due to a mechanical gaping or stiffening of the pylorus, allowing the food to empty out of the stomach rapidly. Hypermotility may also indicate duodenal, gall-bladder, cecal, or appendical irritation.

The peristalsis of a carcinomatous stomach very frequently shows certain departures from the normal. Peristaltic vigor is usually in proportion to the degree of acidity; high acidity indicates sharp peristalsis, and with low acidity the peristalsis is diminished. When the pylorus is obstructed frequently a vigorous effort at compensation is made by the stomach as is shown by strong contractions, thus demonstrating Nature's effort to overcome the stenosis. Therefore, in a non-malignant obstruc-

Fig. 6—Chronic perforating ulcer of the lesser curvature with organic hourglass contraction of the stomach. Pain points and adhesions are elicited by palpation under screen.

tion, such as the cicatricial scar of an old ulcer at the pylorus, a dilatation of the stomach walls is often found and is a characteristic symptom. Of more importance in malignant conditions, a peristaltic wave may be interrupted by malignant in-

filtration of the stomach walls. A wave will approach an affected area, seem to be quiescent, and then resume its action beyond the diseased portion. Lessened mobility of the stomach occurs as a result of the malignant process invading the surrounding

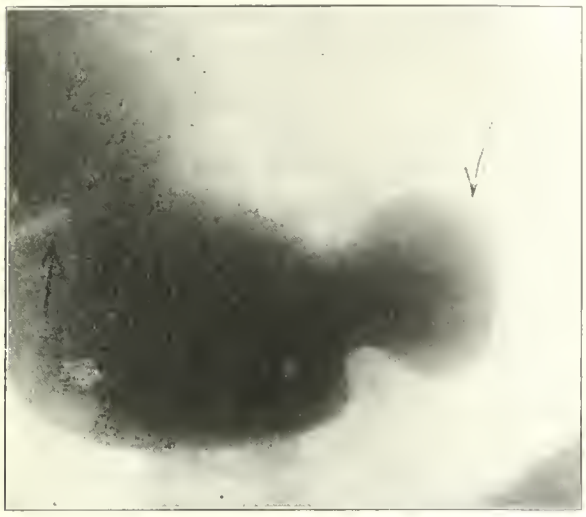

Fig. 7—Pyloric stenosis on basis of callous ulcer; large residue, 6 hours and 24 hours. Dilatation of stomach, with incisura or spastic indrawing of the greater curvature.

tissues. Diminished flexibility of the stomach walls may be noted by palpation so that the stimulating action of massage has no effect on the peristalsis. The subject of antiperistalsis has been studied by such well-known authorities as Haudeck, Groedel and others. It is an *x*-ray storm center. It has never been found in an organic sound stomach and in every case where operative procedure has followed there has always been a definite alteration of the stomach. It is usually found in pyloric stenosis caused by an old ulcer or early carcinoma. It is a valuable sign, but of minor significance.

The question of malignancy of a given condition is always for the pathologist to determine, but the characteristics are so definite and have been reasoned out and proven by so many noted authorities, that cancer can now be diagnosed radiologically in 95 per cent. of cases. A pretty good record for a diagnostic method that has received so much criticism at the hands of some of the profession. Unquestionably the Röntgen ray will materially aid in the correct diagnosis of a disease that attacks the stomach more than any other organ of the body. Valuable information can be given whether an operative measure should or should not be advised, and much suffering and the expense of a fruitless operation be saved the patient. It also offers a better prospect for earlier surgical intervention whereby many lives may be prolonged five, ten, or fifteen years.

The Radiological Signs of Gastric Ulcer.—They may be classified as those that are pathognomonic and those that are suggestive.

The cardinal signs are: Visualization of the bismuth-filled crater (Haudeck's niche). The diverticulum of a perforating ulcer. Organic hourglass stomach with lateral canalization.

The suggestive signs are: The spastic contraction on the greater curvature (incisura). This sign, according to Case, may be indicative of duodenal irritation; it may also show as a reflex irritation from gall-bladder and cecal disease. Snail or hook form of stomach with displacement of the pylorus to the left and down. Prolonged spasm of the pylorus early; duodenal ulcer gives a late spasm. Tender pain point over the area of the lesser curvature. Residue after six hours. Tendency to hypotonic or subtonic stomach. Exaggerated peristalsis.

A bud-like projection or niche on the outline of the bismuth-filled stomach corresponds to the crater of a callous ulcer and is a definite and positive sign. It is usually found on the lesser curvature, and it is called by some authors a chronic penetrating ulcer. This small pocket is formed by an erosion of the mucous membrane down to the peritoneal lining. It is practically the first stage of a chronic perforating ulcer, but it has not excavated its way through the peritoneal coat. When this stage progresses and the irritation continues, the ulcer finally excavates its way through the peritoneal coat and a chronic perforating ulcer with a pouch or diverticulum is formed. The perforation may continue to the liver region or push its way to the pancreatic area. These diverticula vary from the size of a hazel nut to that of a golf ball, and have at times given rise to the diagnosis of an accessory stomach by some earlier investigators. A diverticulum will frequently hold a residue after six hours and also contain an air bubble. It is called the niche (Nischen) sign by Haudeck, who originally described the interesting condition.

Whether the perforation is on the liver or in the pancreatic region can be determined by the fluoroscopic screen; with the liver it shows movement with respiration, but in the pancreatic region no such movement is seen. An oblique view under the screen is of advantage.

Organic hourglass contraction of the stomach frequently accompanies this condition; it can be differentiated from the spasmodic type by persistence after palpation and the administration of an antispasmodic. Organic hourglass contraction is somewhat irregular in outline and the walls are apt to

Fig. 8—Scirrhus carcinoma of the pylorus with stenosis and retention. Operable. Observed by fluorescent screen or plate.

be stiffened; it also is associated with an organic change of the stomach walls such as a carcinoma, a perforating ulcer, or syphilis.

The incisura or spasmodic indrawing of the greater curvature has been held by some as a posi-

tive sign of gastric ulcer, but recent observers, such as Case of Battle Creek, have contended that it may be associated with duodenal irritation as well as that from the gastris mucosa. Personally I have also noticed this symptom in a case of old

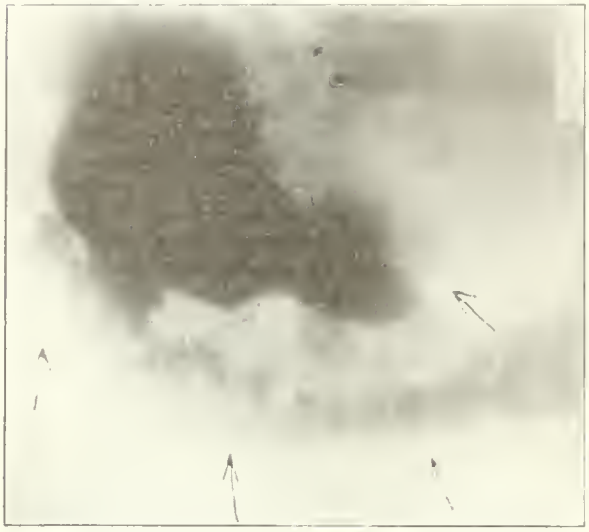

Fig. 9—Early carcinoma of pylorus with hypermotility. Six-hour meal in the transverse colon, splenic flexure and descending colon. No residue at 6 hours.

callous ulcer of the pylorus with dilatation. Carman states it is always found on the greater curvature opposite the point of irritation, but my experience along with that of others shows that it may come from anywhere in the gastric or duodenal region. A true incisura is distinguished from a peristaltic wave by the fact that it does not move toward the pylorus, the spastic indrawing remains in one place, it will persist after vigorous palpation, and is not effaced by the administration of an antispasmodic. Pressing the stomach upward will often remove an indenture caused by the gas-filled colon or the spleen. This condition should not be mistaken for an incisura. Incisura are frequently situated high up in the stomach and as ulcerous stomachs are often of the hypotonic variety it may fail to be seen unless the patient lies down, which allows the bismuth mixture to fill completely the stomach lumen. False incisura may be caused by other reflex causes, but they usually move toward the pylorus and disappear on manipulation. Carman reports a case in which a persistent indrawing of the stomach was due to a mesenteric band passing over the greater curvature and attached to the splenic flexure of the colon. Operation verified the diagnosis.

A hypotonic stomach is not unusually associated with ulcer; it is displaced to the left and down. A scar formation may occur on the lesser curvature near the pylorus and cause the stomach to bend on itself like a snail, hence Haudeck's snail form of stomach notorious in gastric literature.

Delayed opening of the pylorus, in contradistinction to the rapid emptying of duodenal disease, is almost invariably seen in ulcer of the stomach following the administration of the bismuth water. Later pyloric spasm may also be associated reflexly with duodenal, gall-bladder, and cecal disease.

A residue after six hours is very often associated with ulcer, but it may be absent. It has occurred, according to most authorities, in about 75 per cent. of cases; it varies from a small portion to one-half or one-fourth of the meal, and according to the amount of disease involvement. Most authors claim the residue is due to the spasm of the pylorus retarding the evacuation of the stomach. The writer has frequently seen a residue with nothing but an atonic condition of the stomach walls; that is to say, congenital visceroptosis may cause a residue with absolutely no pathological findings.

A localized pain pressure-point over the gastric area is not a positive sign, as many persons are sensitive over the epigastric region. Unless the parietal peritoneum has been punctured as in a penetrating or perforating ulcer, the conditions are rarely acutely painful, but if a pain-point is definitely localized it is of much importance in the final summing up of the diagnosis. Notwithstanding the many signs, both positive and suggestive of ulcer of the stomach, there is a small number of cases in which signs are absent, especially such cases as the florid type of ulcer in the pars pylorica and the stomach wall. In these cases the clinical evidence will help to clear up the diagnosis.

The radiological signs of duodenal ulcer are not so clean cut and definite as those of gastric ulcer. They are, however, of sufficient importance, from a fluoroscopic as well as a radiographic standpoint, that a positive diagnosis can be made in nearly all cases.

The signs may be classified as those that are static and those that are functional. A diagnosis of duodenal ulcer, I belive, is largely made on the functional signs.

The symptom complex of duodenal ulcer is as follows: Quick emptying of the stomach; hypermotility, or the advance of the bismuth meal into the transverse colon in six hours; hypertonic or orthotonic stomach; late pyloric spasm; incisura

Fig. 10—Upper arrow points to obscure gastrointestinal disease discovered by palpation under the fluorescent screen. Patient examined recumbent. Adhesions of the hepatic flexure of the colon and adjoining region. Prolapse of the transverse portion of the colon on the ascending colon with possible adhesions. Lower arrow points to high cecum and clearly visible appendix which has emptied some of its contents. Diagnosis, old gall-bladder disease, adhesions of the colon in that region, and colonic stasis, due to mechanical stricture.

or spastic indrawing of the greater curvature; marked antral activity of the pyloric antrum; pain-point over the duodenal area; defect in the cap; a small residue in the duodenum or stomach; in the stomach the residue is due to a late pyloric

spasm, a reflex symptom of duodenal irritation; distended bulbus duodeni indicative of constriction of the duodenum in its descending portion.

In duodenal conditions it is frequently necessary to take a number of plates, especially if the patient is large and muscular.

I contend it is not always necessary to have a defective cap to diagnose a duodenal ulcer. An ulcer of the florid type may exist and absolutely no defect in the bulbus duodeni be visible. These ulcers may also be serious from a hemorrhagic standpoint. An ulcer of the florid type can be diagnosed only from its functional and radiological signs and not from any deformity.

A defect in the duodenal bulb is frequently due to old gall-bladder adhesions or periduodenitis. A scar of an old healed ulcer often gives less annoyance than an acute ulcer of the florid type, and it is certainly less dangerous.

Quick emptying of the stomach, hypermotility, deformity of the bulbus, late pyloric spasm, and marked antral activity are the cardinal signs of duodenal irritation.

As suggestive signs we may consider: Pain-point over the duodenal area; hypertonic stomach; the incisura or spastic indrawing of the greater curvature; diminished peristaltic activity of the stomach (gastric ulcer has increased peristalsis). Peristalsis of the duodenum is increased, and upon examination with the screen the duodenum will often show a twisting or serpentine motion of the ascending and descending portions. The fluoroscopic screen is the moving picture show of the normal as well as the abnormal activity of the esophagus, stomach, and the intestines, and it has only one rival—the serial plate method or cinematograph, as originated by Rosenthal of Germany and carried to a high degree of perfection by Cole of New York.* The time and expense of exposing and developing forty to eighty plates of a single case, with a few exceptions, offer an effectual bar to its universal adoption. *The localizing of adhesions and pain-points by palpation with the patient standing or recumbent, which is always part of a screen examination, is certainly impossible by the serial plate method.* Pirie of Montreal has recently evolved a method in making six to sixteen separate exposures on a single 14 x 17 plate; this involves much less labor than the taking of a series of forty to eighty plates.

The radiological examination of the small and large intestines has reached a degree of precision that would seem uncanny. Such diseases as cancer, stricture, stasis, colitis, displacements of the small and large intestine, appendicitis, cecal adhesions, Lane kinks, and ileocecal incompetency, can be located and definitely diagnosed both fluoroscopically and with the plate. In the above conditions the fluoroscopic examination is invaluable, and no other method can equal the exact and precise information gained by palpation of the abdominal viscera with the fluoroscopic picture of the bismuth-filled bowel on the screen. Extensive studies of visceral peristalsis can be made only by this method. Holzknecht of Vienna has of recent years aided enormously to the literature of the day by his extensive researches on the peristaltic activity of the large and small bowel. Case of Battle Creek and Jordan of Lane's clinic have largely followed his original technique in their more recent investigations.

Cancer of the bowel is rare; in 41,838 autopsies at the Allgemeines Krankenhaus in Vienna from 1870 to 1893 there were 3,585 cases of cancer; 343 were in the intestine, 164 in the colon, and 162 in the rectum. The possibility of the discovery of cancer in the colon is not striking, but the disease has been so often overlooked that the diagnostician cannot afford to be careless. Many other conditions not thought of can be discovered in a routine examination of the intestines when trouble is thought to have its origin in the large or small intestines.

From what has been said it can be seen that the radiological signs of the surgical and medical lesions of the gastrointestinal tract assume a most important standing when a diagnosis is to be made. Diagnosis should not rest on the *x*-ray findings alone; the Röntgen ray simply furnishes valuable contributory evidence as to the presence or absence of a lesion. The radiologist of necessity must be a clinician, pathologist, and anatomist, and be able to follow his cases to the operating room and take his full share of the responsibility. What we need is cooperation and first-class team work—the conjoint action of the clinician, radiologist, and surgeon; then a definite and positive measure of success can be attained.

The radiology of gastrointestinal diseases is in its infancy, but with enthusiasm and conservative judgment it will attain high rank as a diagnostic measure and be demanded as a necessary procedure before operative interference. With the exception of gynecological diseases the Röntgen ray has, I believe, displaced the exploratory operation. Truly science has advanced if we have diminished the necessity of exploratory operations.

*As early as 1900 Cavallio of Paris was able to obtain cinematograph pictures which showed the movements of the stomach and the intestines in animals. In 1901 Eykeman made the original cinematograph radiographs of the act of deglutition.

THE EXCISION OF THE FISTULOUS TRACT IN THE TREATMENT OF FISTULA IN ANO.

By CARLO SAVINI, M.D.,

NEW YORK.

AN observation, even superficial, of the structure of the fistula in ano is sufficient to convince one that the best way of treating this disease is by the extirpation of the fistulous tract. The total excision is superior to all the various procedures advocated for the treatment of this condition for many reasons, and whenever it is possible it should be considered as the method of choice.

It is a rational operation; it permits a plastic suture of the sphincters, and so reduces to a minimum the dangers of incontinence, and by removing all the pathological structures produces a radical cure in the shortest period of time.

The fistulous tract is in reality a tumor, and as such should be totally removed. The fistula is

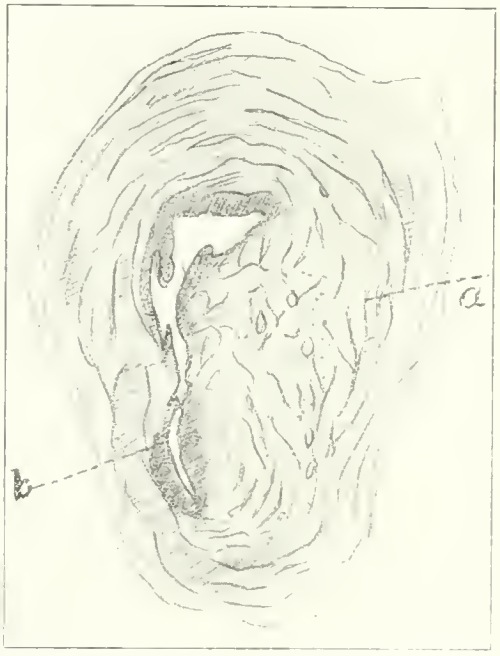

FIG. 1.—Transverse section of the fistulous canal. *a*, fibrous tissue. *b*, granulations.

essentially formed of a tube of hard fibrous tissue lined with granulations. The limits of this tube are very well defined, and its adhesions to the surrounding muscular fibers of the sphincters can be easily separated and dissected.

On the microscopical examination of a cross-section of the specimen we find that the fistula consists mainly of a tube of fibrous tissue perforated by a great quantity of blood-vessels passing from the external to the internal part of the tube. In the inside of the tube these vessels form capillary loops and pedunculated tufts like hemorrhoidal nodes. The abundance of blood-vessels and the fibrous tissue are the main features of the structure.

The skin around the opening of the fistula is also affected, and should be removed with the fistula. If the specimen is cut lengthwise we find that at the level of the external opening of the fistula the rete mucosum or Malpighian stratum of the skin is thickened and shows proliferation of the epithelial cells into the derma. Some sections give the appearance of a squamous epithelioma, and we find also the concentric globes or pearls which in the past were considered characteristic of squamous epithelioma. In my opinion the introflexion of the

FIG. 2.—Longitudinal section of a fistula; *a*, fibrous tissue; *b*, granulations; *c*, Rete mucosum of the skin; *d*, pearls; *e*, vascular tissue in the internal part of the fistula.

epithelium and the pearls are the remnants of the cicatrization of old fistulous openings now obliterated.

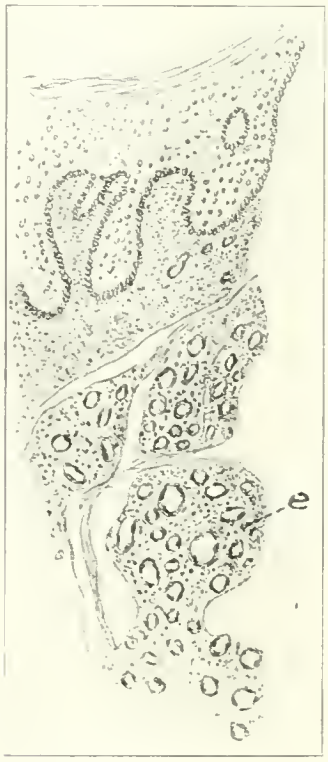

FIG. 3.—Enlarged view of the preparation of figure 2; *e*, vascular tissue in the internal part of the fistula.

The epithelium of the skin ends abruptly at the level of the opening of the fistula. No epithelial lining is found in the internal part of the fistula.

It is impossible to understand how this structure could be cured by simple incision and curetting.

As for the danger of incontinence of the sphincters following the operation for fistula in ano it is necessary to recall some anatomical details of the rectum. The internal and external sphincters surround the last portion of the rectum, the pars analis recti; but while the internal sphincter covers this pars analis in all its extent, the external sphincter occupies only a small part of it. The relative extent of the two muscles is very important, and it is well demonstrated by Fig. 4, which shows semischematically the disposition of the muscular coats of the rectum, according to the researches of Roux. It is clear in this figure that the circular fibers of the internal sphincter are a continuation of the circular muscular fibers of the intestine, and completely encircle the pars analis in its entire length, and the external sphincter covers only the most external portion of the pars analis.

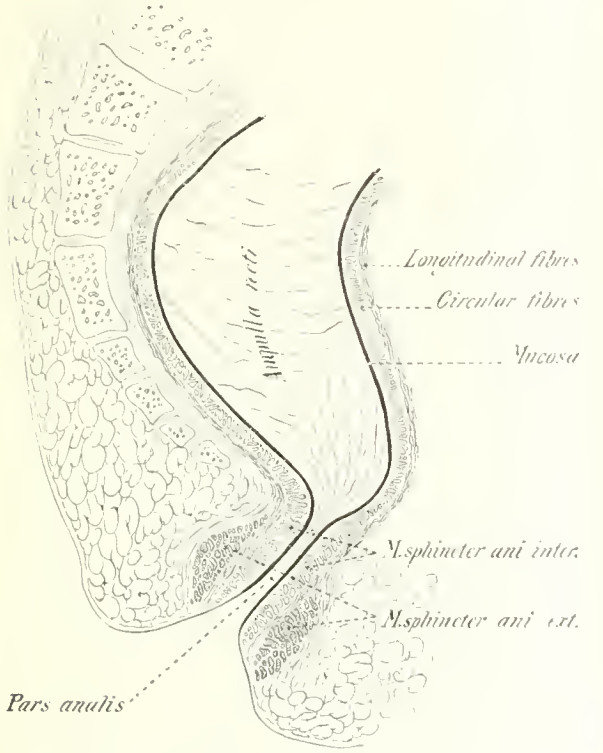

Fig. 4.—Schematic section of the rectum.

The fistula usually affects only a small part of the sphincters, so that, even if the part of the sphincters intervening between the fistulous tract and the mucosa is cut and not repaired, we have always enough sphincter left to keep the anus continent.

The incontinence following the operations for fistula in ano is not due to the incision of the sphincters, but it is more the consequence of the divulsion of the anus preceding the operation. When the stretching is not carefully done, or when it is done too roughly, it may cause rupture of the muscular fibers, interstitial hemorrhages, and consequent atrophy of the sphincters and incontinence.

The Operation.—The day before the operation the patient is given a cathartic and enemas to empty the bowels entirely. The perineum is shaved. The patient is put under general anesthesia and placed on the table in the lithotomy position.

The operation consists of three steps:

First. The stretching of the sphincters. This must not be attempted until the patient is under complete and deep anesthesia, and must be very gently done with patience and time, and using only the two index fingers. To use force is absolutely

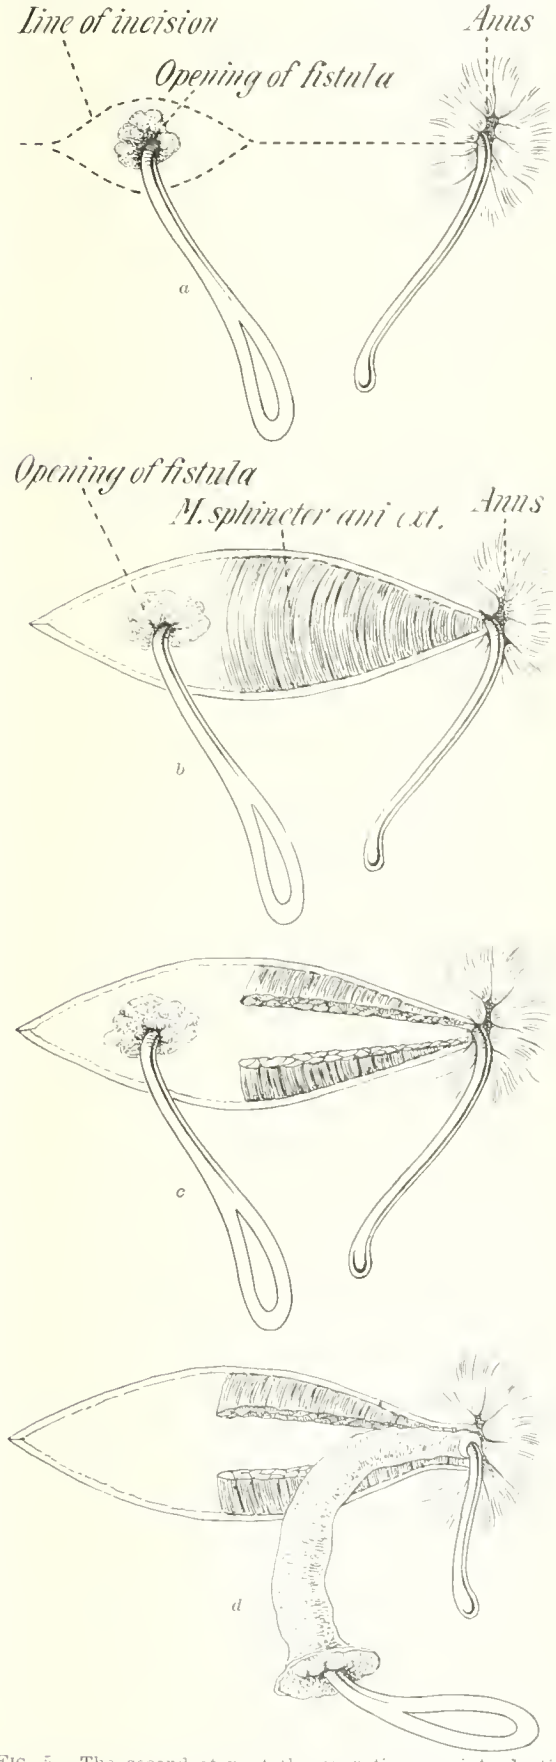

Fig. 5.—The second step of the operation. *a*, introduction of the probe; *b*, incision of the skin; *c*, incision of the sphincter; *d*, exterior of the fistulous canal.

dangerous. The stretching must not be overdone. It is sufficient to overcome the resistance of the muscles without exceeding the limits of elasticity of the muscular tissue. Besides it is not necessary to stretch all the pars analis, but only up to the point that we see the internal opening of the fistula.

Second. Excision of the fistulous tract. After the sphincters have been stretched a small gauze sponge is introduced into the rectum to prevent the feces from coming into the field of operation. A silver probe is then introduced into the fistulous canal, and with the help of the index finger it is made to pass through and protrude from the anus. The probe can be bent to act as a retractor and

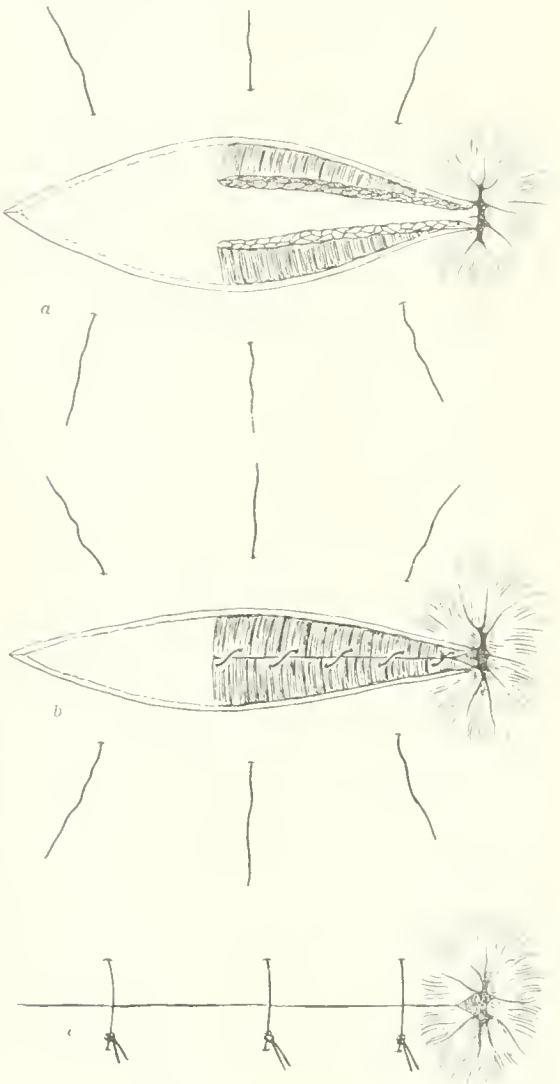

Fig. 6.—Third step of the operation; *a*, the silk sutures in place; *b*, the muscular suture completed; *c*, the operation completed.

bring the fistulous tract into evidence. An elliptical incision of the skin is made around the opening of the fistula, and a straight incision is made in the direction of the fistula to the rectum.

The skin, the mucosa, and the sphincters are now cut in regular order over the fibrous tube of the fistula. The tube is exposed and dissected from the adjoining tissues, and with the help of the probe the fistula is removed unopened. This dissection is not difficult, and may be done partially with the use of a blunt instrument. Very few vessels require ligature.

Third. Suture. Starting about one-half inch from the anus the wound is sutured with three or four interrupted stitches of silk, the silk being buried in the deep tissues through the whole course of the stitch, but these sutures are not tied until the end of the operation. The incisions in the sphincters are now closed with a continuous suture of fine chromic catgut threaded in a small needle, and when this muscular suture is finished the skin sutures are tied. No suture is applied to the mucosa of the rectum, so that in the side of the anus the wound gapes open for a little space and is drained.

A large rubber tube covered with gauze and abundantly smeared with vaseline is placed in the rectum with the aid of an anal speculum. The skin suture is dressed with mercurial ointment and sterile gauze. This antiseptic insures a rapid healing of the wound.

The rectal tube is removed after twenty-four hours; the silk sutures on the tenth day. A cathartic is given three days after the operation. The wound is generally healed in about three weeks.

THE TREATMENT OF TYPHOID FEVER WITH TYPHOID VACCINE ADMINISTERED INTRAVENOUSLY.

By HELEN I. McWILLIAMS,

NEW YORK.

(From the Quarantine Laboratory, Port of New York, Health Officer's Department.)

Typhoid vaccine was first administered intravenously as a therapeutic measure in typhoid fever by Ichikawa in Japan, who described his method in April, 1912. He published in May, 1914, a full report covering 82 cases treated in this way. His vaccine was prepared by treating living typhoid bacilli with the serum of patients convalescent from typhoid fever, by washing the bacilli several times, and adding carbolic acid to 0.3 per cent. He described a critical drop in the temperature, and a truly remarkable improvement in the condition of the patient within twenty-four to forty-eight hours after the injection of this vaccine. About half of the patients treated entered at once upon convalescence; others either failed to respond or showed only a temporary fall in temperature, but the author thought that the course of the disease was shortened in these cases also. The death rate in these cases seems high (12 per cent.), but his control untreated cases showed a mortality of 30 per cent. Prof. R. Kraus and his co-workers in the Argentine Republic obtained similar results entirely independently of Ichikawa, and published their first reports a few months after the latter's full report had appeared. Since then the intravenous injection of vaccine has been used in treating typhoid fever by a number of men in Europe, particularly in the war hospitals, and by F. P. Gay in this country.

Table I presents a brief summary of the number of cases treated by each of these observers and of the results obtained so far as can be ascertained from their published reports.

Most of the cases tabulated in the column "Cured" were instances of complete recovery by crisis; some of them showed a slight rise of temperature several days after the crisis; others did not respond promptly to the injection, but it seemed clear from the author's description that the course of the disease had been shortened. In other words, those

*Majority of cases received two or more injections.

instances of recovery in which the disease apparently ran its usual course uninfluenced by the intravenous injection of vaccine are not recorded as "Cured."

The percentage mortality in itself offers but little evidence as to the danger or efficacy of the treatment, as it will necessarily vary according to whether only mild cases, only severe cases, or all types of cases are subjected to the injections. The highest death rate, 23 per cent., was observed by Paulicek. His patients were soldiers who had suffered from severe exposure in cold weather, and they died in most instances from a complicating pneumonia. The high mortality of 23 per cent. represents, he says, a reduction by 20 per cent. from what was obtained without the injection of vaccine. It has already been mentioned that the death rate in Ichikawa's control cases was more than twice as high as in the treated cases.

Of far greater importance than the percentage mortality is the question as to how many, if any, of the deaths could be attributed directly to the action of the vaccine. Five cases (treated by Boral, by Csernel and Marton, by Löwy, Luksch and Wilhelm, and by Paulicek) showed intestinal hemorrhage following the injection and terminated fatally. One case (of Sladik and Kotlowski) resulted fatally from hemorrhage into the thyroid gland. One of Eggerth's patients developed a hemorrhage from the lungs and died three hours after the injection. One of Biedl's had hemorrhage from the nostrils before the intravenous injection of vaccine was given: after the treatment the hemorrhage recurred and could not be stopped.

All these persons may have died from hemorrhage induced by the injection. This suggests that hemorrhage should serve as a contraindication to the use of vaccine intravenously.

Koranyi attributed one of his deaths to the vaccine, but thought that he had administered too large a dose. Finally, two of Eggerth's patients, who were suffering from pneumonia in addition to the typhoid fever, died three hours after the injection of the vaccine. One of Holler's patients who received an intravenous injection of Besredka's vaccine and upon the following day an intravenous injection of Vincent's vaccine went into collapse and died, showing symptoms of heart failure. Hence it should be ascertained that the heart and lungs are in good condition before the treatment is given.

Of these twelve patients whose deaths may have resulted directly from the injection of the vaccine five received Besredka's vaccine, four received Vincent's vaccine, and one received both of these vaccines. No death has been attributed by the authors directly to the injection of vaccine killed by heat.

The dosage used has been 100 to 300 million of Besredka's vaccine; 100 to 300 million of Vincent's vaccine, and 250 to 750 million of vaccine killed by heating.

The cases receiving the same type of vaccine are grouped together in:

TABLE II.

Kind of Vaccine	Number of Cases Treated	Cured, per Cent	Mortality, per Cent
I. Ordinary typhoid prohpylactic. (Typhoid bacilli killed by heating)	165	53	2
II. Vincent's vaccine. (Typhoid bacilli killed with ether)	129	64	28
III. Besredka's vaccine. (Living sensitized typhoid bacilli)	101	83	8
IV. Other vaccines	161	75	14

Here again the percentage of "cures" does not include the recoveries in which the course of the disease was apparently uninfluenced by the vaccine, whereas the percentage mortality includes all deaths —even those resulting from lobar pneumonia, tuberculosis or other causes not connected with the typhoid fever or the vaccine treatment.

It is obvious from Table II that the observations thus far made do not show that any one type of vaccine has any great superiority over the other types. The number of cases treated is not yet sufficiently large for the percentages of cures and percentages of deaths to be taken at their face value. There is an indication that the Besredka vaccine yields slightly better results than the others.

Several hypotheses have been advanced to explain the mechanism of the rapid recovery of typhoid patients after the intravenous administration of vaccine. The suddenness of the reaction (consisting in a chill in 20 to 40 minutes after the injection with a rapid rise in temperature followed by a drop to normal within 24 hours) suggests at once anaphylaxis, and Ichikawa was inclined to regard the phenomenon in this light; the intravenous injection of typhoid bacilli would bring about an anaphylactic reaction in the patient already sensitized to the proteins of the typhoid bacillus; the patient would then enter upon a condition of insusceptibility (antianaphylaxis) to these same proteins.

Gay found that rabbits immunized against the typhoid bacillus responded to an intravenous injection of typhoid bacilli with amarked leucocytosis. He claimed that this reaction was specific and that it was often transitory, so that it might escape notice unless the leucocyte counts were made at one-half to one hour intervals. It seemed possible, therefore, that such a specific leucocytic response might be responsible for the recovery of typhoid patients following an intravenous injection of vaccine. With the idea of throwing some light upon this phase of the subject we decided to give a typhoid patient a full dose of vaccine intravenously and then to make leucocyte counts of his blood at one hour intervals until he had passed through the reaction.

With the consent of the health officer, Dr. O'Connell, an only moderately severe case of typhoid fever in the Quarantine General Hospital on Hoffman Island was selected for treatment. The patient was a man 27 years old and had been ill nine days. A blood culture in bile taken two days before the administration of the vaccine was negative but typhoid bacilli were recovered from the stool obtained on that same day. The Widal reaction was positive. Five hundred million typhoid bacilli killed at 56° C., the initial dose of the typhoid prophylactic put out by the New York Department of Health Research Laboratory, were injected into the median vein at the elbow. Thirty-five minutes later the patient had a severe chill and his temperature rose rapidly, reaching 106.4° three hours after the injection. It remained in the neighborhood of 105° for twelve hours and then rapidly fell to nearly normal during the next twelve hours. During the next seven days the temperature remained below 100°. The patient had in the course of twenty-four hours been transformed from a sick typhoid patient into a convalescent. As is indicated by the high temperature, the reaction was very severe, but the pulse at no time assumed an alarming character, according to Dr. Stanley B. Doyle, the resident physician, to whom we are greatly indebted for his assiduous care of this patient and also of the second one during the reaction period.

A leucocyte count was made just before the vac-

cine was administered, and then regularly at one hour intervals until the temperature had reached normal. Smears of the blood were made at the same periods and preserved for differential counts. A full record of these counts is given in Table III.

Curves of the leucocyte counts and the temperature are plotted upon the same chart, and will be discussed together with similar curves from our second case.

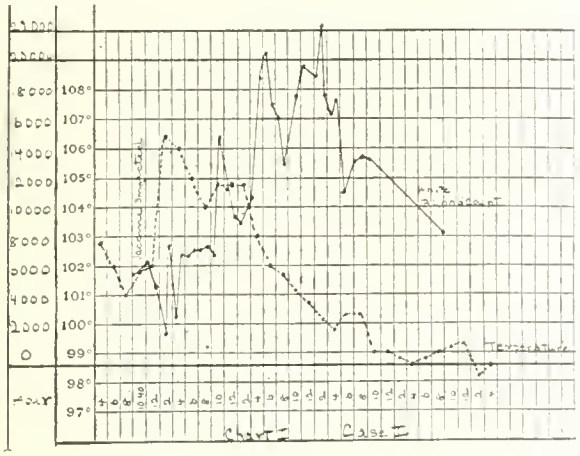

Chart 1.

In order to show which variety of white cells is most affected by the increase or decrease in the total number of leucocytes, the number per cubic millimeter of polymorphonuclears (including the eosinophile cells and transitional cells) and of the lymphocytes has been calculated for each period and the results plotted in curves.

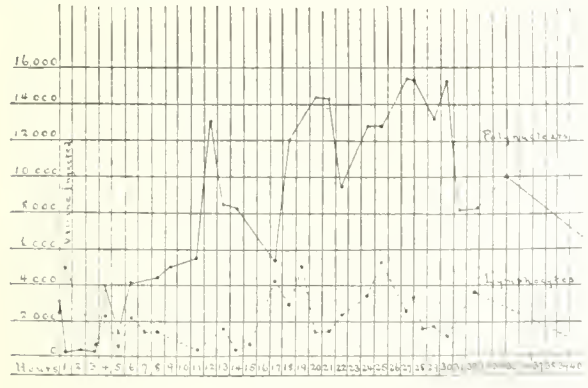

Chart 2.

Before discussing the behavior of the leucocytes in this case, the results in the second case will be presented.

The second patient subjected to the treatment was an earlier and much severer case of typhoid fever, also in the Quarantine General Hospital. He was a man 22 years old at about the fifth day of the disease. A blood culture in bile on the day before the administration of the vaccine was positive for typhoid bacilli. The stool examination and the Widal reaction on the same day were negative; typhoid bacilli were isolated from the stools six days later. The same vaccine as in Case I was used, but a smaller dose, 350 million, was given. The injection was made into the median vein at the elbow as before. Fifteen minutes later the patient had a severe chill, which lasted for ten minutes. His temperature was high at the time of the injection, and rose rapidly after the injection to 107.4°. It remained in the neighborhood of 106° for ten hours and then fell rapidly to normal. The patient talked incoherently in his sleep all night on July 29, received his injection on the morning of July 30, had a high temperature during that day, but slept well all during the night of the 30th. On the following morning his temperature was normal. The effect of the treatment was, however, only transitory. The temperature rose again on the afternoon of the 31st and the disease ran the usual course of a severe typhoid to recovery. The patient had a severe bronchitis, and Holler has called attention to the fact that such cases are often very refractory to the treatment.

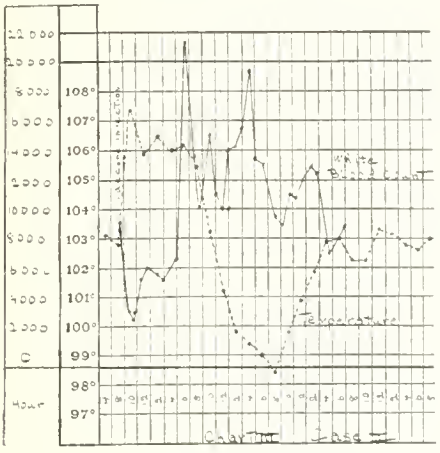

Chart 3.

A full record of the leucocyte counts and differential counts in this case, and also curves of the temperature, total number of leucocytes, and number of polynuclears and lymphocytes are given in Table IV and charts 2 and 3.

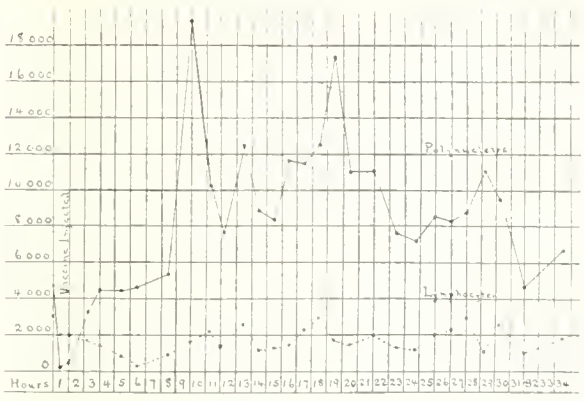

Chart 4.

Both patients showed a marked decrease in the number of leucocytes in the blood a few hours after the injection. In Case I the leucocytes fell from 5800 to 1470 in three and one-third hours, in Case II from 9200 to 2500 in one and one-half hours. After this first drop they rapidly increased in number to more than 20,000 per cubic millimeter in both instances. Such a leucocytosis is very high for typhoid fever cases, which usually show a leucopenia. It is interesting to note that the decrease in the number of leucocytes coincides with the rise in temperature after the injection, and that the increase in the number of leucocytes later on occurs synchronously with the fall in temperature. This is clearly shown in charts 1 and 3. Löwy, Luksch and Wilhelm using Besredka's vaccine and Gay using the killed sensitized vaccine noticed a similar behavior of the leucocytes in their cases. Holler made blood counts in a large number of cases and

observed the marked leucopenia shortly after the injection in almost every instance, but he only rarely obtained a high-grade leucocytosis, probably because his later counts were made at too long intervals. His leucocyte counts in Case VI, which received Vincent's vaccine, resemble ours very closely as far as he carried them. It seems, therefore, that the living sensitized vaccine, the killed sensitized vaccine, the vaccine killed with ether, and the vaccine killed by heating all call forth a similar response on the part of the leucocytes when injected intravenously into typhoid patients.

TABLE IV.

Case 2

Time After Injection	Leucocyte Counts	DIFFERENTIAL COUNTS—Percentage of: Polynuclears	Large Mononuclears	Lymphocytes	Eosinophiles	Basophiles	Transitionals
Before injection	9,200	53	13	32	....	1	1
1 hr	2,800	1	23	74	....	1	1

28½ hrs.	13,000	87 5	1	11 5	....	....	....
29½ hrs.	12,400	78	0 5	21	....	....	0.5
31½ hrs.	6,600	73	7	19	....	....	1
34 hrs.	8,800	78	....	22	....	....	....

Charts 2 and 4 demonstrate that both the leucopenia and the leucocytosis following the treatment are due to variations in the number of polynuclear leucocytes, while the lymphocytes remain comparatively constant in number throughout the reaction period.

The eosinophile cells are much reduced in number in typhoid fever; in agreement with Rhein we find that their number is increased a few hours after the injection of vaccine into typhoid patients.

From the above study the present status of the treatment of typhoid fever with intravenous injections of vaccine would appear to be as follows:

1. More than 550 cases treated in this manner have been reported in the literature.

2. In more than half of these cases the disease was cut short, the patient having been saved from one to several weeks of fever.

3. A few deaths must undoubtedly be attributed directly to the injections of vaccine. However, this is likely to occur with any new and radical method of treatment. As the contraindications and dosage are better understood such deaths should become extremely rare.

4. No one type of vaccine seems to possess any great superiority over other types with regard to treatment.

5. The proper dosage for intravenous injections appears to be from 100 to 250 million bacilli.

6. The injection of the vaccine calls forth first a marked leucopenia and several hours later a high-grade leucocytosis in typhoid patients. Variations in the number of polynuclear leucocytes are responsible for these changes, the lymphocytes remaining relatively constant. The eosinophile cells undergo an increase shortly after the injection.

7. The various types of vaccine call forth similar changes in the blood picture.

ROSEBANK, STATEN ISLAND.

SYPHILIS OF THE LUNG.*

BY M. T. EASTON, M.D.,

PEORIA, ILL.

MY paper this evening is on a condition which, while recognized as a rare one, I personally believe to be more common than is generally supposed. It is based on the report of a case which occurred in my practice.

The history is as follows:

L. M., age 51. Patient was taken with a severe hemorrhage of the lungs during the early morning hours of March 18, 1912, during which time he coughed up a large amount of blood, also a large quantity of a very foul smelling, purulent sputum.

He gives a history of having had during the two weeks previous to this time twenty-one hemorrhages. Has no pains in chest. Has lost about 20 lbs. in six weeks. He also states that he has had more or less of a severe cough for the past four months. Previous to that time was perfectly well.

Past history: Pneumonia, 31 years ago, sick about two weeks. Syphilis, 1905, initial sore on penis. Treatment consisted of inunctions and internal medication, continued only for three weeks. Then took five bottles of some patent preparation. He has had absolutely no treatment since that time.

Family history: Father living, age 84. Mother died at age of 45 of pneumonia. No tuberculosis in family.

Personal history: Married 31 years, five healthy children. Occupation: Bartender. Drinking habits are moderate, although he has always been associated with the liquor trade. Infected his wife with syphilis shortly after he contracted it, eight years ago.

Examination showed well nourished man of 51 years, slightly anemic, temperature 100°, pulse 80, regular and full. No skin eruptions.

Regional examination: Head and neck, negative. Scalp, negative. Eyes show sluggish pupils, but not Argyle-Robertson reaction. Nose, negative. Ears, negative, except for scar over the left ear due to injury received in a fight many years ago. Mouth and throat negative. Neck shows no glandular enlargement.

Chest: Inspection, negative. Palpation: Increase of tactile fremitus over area of about the size of one's hand, over the right lower lobe posteriorly. Percussion of apices negative; dullness over the above-mentioned area, with hyperresonance around the border. Auscultation: Bronchial breathing over the above-mentioned area, together with moist râles, and signs of cavity formation, otherwise chest is negative.

Abdomen: Liver, stomach, spleen, intestines, etc., entirely negative.

Genital: Scar on penis showing site of old chancre, otherwise negative.

Arms and legs: Negative.

Nervous: Complete absence of patellar reflexes. Shows Romberg's sign slightly, otherwise negative.

Urine examination: Reaction, acid; specific gravity, 1,022; albumin absent; sugar absent, microscopical negative.

Sputum examination: Repeated examinations of the sputum, six in number, made by me, showed total absence of tubercle bacilli. The patient informs me that he had also had his sputum examined in other cities at various times, always with a negative result. Moro skin reaction was absolutely negative.

Diagnosis: At first the case was regarded as one of tuberculosis. After I had seen the patient three times he moved to his home at Bushnell, Ill., and placed himself under the care of Dr. Geo. Duntley of that city.

*Read at a meeting of the Peoria County Medical Society, June 3, 1915.

On a visit to this city, Dr. Duntley and I discussed the case and concluded to put him on antisyphilitic treatment, thinking possibly that it might be a gumma. Our diagnosis was based on (1) Repeated absence of tubercle bacilli in the sputum. (2) Loss of knee reflexes and sluggish pupils as evidence of syphilitic involvement in other organs. (3) Physical findings absent in both apices and present only in the lower lobe of the right lung.

These points leading to the diagnosis, we hoped to corroborate them by the therapeutic test.

Treatment: The patient was put under treatment of sodium cacodylate, 3 grains administered hypodermically every day for a time, then every second day, by his physician in Bushnell. After a few injections he returned to Peoria and I continued the same line of treatment. After about 15 injections a marked improvement was noted in the patient's condition. His hemorrhage entirely ceased, his sputum became less, and finally his cough disappeared. Examination of the affected area of the lung at this time showed no moist râles, no harsh breathing, and only a small amount of dullness present.

The patient has remained in Peoria ever since that time and I have had frequent opportunities for examination. A recent examination of the lung shows only a few, faintly heard moist râles, over the area which was affected, which I have concluded to be due probably to a bronchiectatic condition in some of the smaller bronchial tubes, due to contraction of scar tissue forming at the site of the old gumma.

There are no changes on inspection, percussion, or palpation. The patient feels fine, has no hemorrhages, and has gained much weight, has no cough and no pains. He has, however, developed a typical Argyle-Robertson pupil, marked ataxia, and has occasional tabetic lightning pains.

The Wassermann test, which was not available on account of financial conditions at the beginning of treatment, but which was done after the patient's recovery, showed a positive reaction.

The patient is in great fear lest his condition return and I give him occasional courses of injections of sodium cacodylate, which in this case has proven very effective.

In olden times, prior to the discovery of Koch's bacillus of tuberculosis, cases of pulmonary tuberculosis were sometimes designated as syphilis, most of which were undoubtedly tubercular.

Virchow, in 1865, states that authors of the seventeenth and eighteenth centuries spoke frequently of phthisis, as lues venerea, and of its cure by antisyphilitic measures. Others, and especially Laennec, opposed this view, holding that tuberculosis was the sole cause of phthisis. However, it was not doubted that syphilis of the larger air passages existed, especially syphilitic laryngitis, but they hesitated long in believing that true syphilitic phthisis could exist.

In 1851 Depaul described the lungs of congenital syphilitic children, which on section showed nodules containing pus. Virchow, however, regarded these as a form of pneumonia and not syphilitic.

In 1862 Virchow had a case in his clinic, on which an autopsy was held, which showed syphilitic conditions of the tibiæ, subcutaneous tissues, lungs, and pleura. On section these lungs were found to contain multiple nodules, the largest being the size of a walnut, with softened centers, oftentimes bronchiectatic cavities being found. This case, together with a few cases of congenital syphilitic infants, showing nodules on the pleura or in the lung substance around the bronchi, which were found to be syphilitic, convinced him of the possibility of syphilis attacking the lungs.

White hepatization of the lungs, an affection found in congenital syphilitic infants, was described by Virchow in 1847, also by Weber in 1842.

In 1854 Hecker was the first to show the relationship of this to syphilis, and later Lorain and Robin found the same condition of white hepatization in a case of pemphigus syphiliticus, which went to autopsy.

According to Dieulafoy, syphilitic conditions of the lungs are divided into the following classes, according to their chief manifestations: (1) bronchopneumonia of a tuberculous aspect; (2) cavities, simulating phthisis; (3) gangrene; (4) fibrosis of the lungs, with dilatation of the bronchi.

He states that he has found syphilis to attack the lung only in the later stages, the bronchial involvement always being an earlier manifestation.

Pathologically, the involvement may be in the form of gummata, diffuse syphiloma, or fibrosis.

Dieulafoy makes the following classification of the various forms of syphilitic affections of the lung:

1. A form with an acute course, very rare, is described, exactly like acute pneumonic phthisis. This involves nearly always the right side, and is diagnosed only by the presence of other syphilitic lesions and continued absence of the tubercle bacillus in examinations. It is very rare and while it should be mentioned, is of such great rarity as almost to be disregarded.

2. Diffuse syphiloma of the lung, or syphilitic bronchopneumonia, occurring almost always in the earlier stages.

3. Syphilitic gummata, resembling chronic tuberculosis. These cases are similar to the one reported by me in this paper. Dieulafoy has found these patients to have little fever, a good appetite, little wasting, frequent cough, some dyspnea and pain, purulent expectoration, and occasional hemorrhages. In the late stages of the disease the physical findings are those of cavities, with bronchial or cavernous breathing. This form of pulmonary syphilis occurs most often in the lower and middle lobes of the right side of the chest.

4. Pulmonary syphiloma with fibrosis or sclerogummatous lesions. In this condition the lung at autopsy is found hard on section and palpation, the pleura is thickened, and on its surface is found cicatrices, similar to a syphilitic liver. Gummata may coexist and be found at different places throughout the lung. The symptoms of this condition are those of chronic bronchopneumonia and bronchiectasis, with no preexistent cause—such as pertussis or measles.

5. White hepatization—a rare condition, found in syphilitic infants, which will be only mentioned and not taken up completely in this paper.

6. Syphilitic gangrene of the lung—an extremely rare condition, which is reported in two or three autopsies.

7. Syphilitic pneumopathy, or the coexistence of pulmonary tuberculosis. It is a well-known fact that syphilis predisposes to tuberculosis.

James Nevins Hyde states that the lung may be the seat of syphilitic infiltration, affecting usually one side of the chest. Gummata very rarely form in the apex, but are found in all other parts of the lung. They consist of grayish, semisolid masses, varying from pea to hen's egg size and surrounded by a fibrous capsule and later undergoing caseation. Softening progresses and finds exit in a bronchus, or resorption may take place, leaving a fibrous mass with a cheesy center. The pleuræ and bronchi are either involved in the same process or exhibit irritating effects of the pulmonary neoplasm.

Microscopically, Hyde has found the center to

consist of granular connective tissue in process of degeneration, and refractive granules. External to this is fibrous tissue. Around the whole is small cell infiltration. Sometimes a protective connective tissue capsule is formed, but in cases in which the action of the virus is intense, necrosis occurs before this capsule has time to form.

Osler in his "Modern Medicine" gives the following description of acquired syphilitic lesions of the lung:

1. Gummata. These are rare, involve the lobes and lower lobe most frequently. They are hazelnut to hen's egg in size. They soften and break into the bronchi or may undergo sclerotic changes, leading to shrinkage of the lung and bronchiectasis.

2. Bronchopneumonia. Osler refers to an autopsy described by Delephine and Sisley, in which an enormous gumma of the right lobe of the liver was found, pushing up the diaphragm, to which it was adherent, extending through and involving the lower lobe of the lung. There were patches of a caseous pneumonia and others looking like a catarrhal or bronchopneumonia, with which findings there was also sclerotic induration. This lesion was an involvement by direct extension and is not a true bronchopneumonia.

A diffuse infiltration is described by Rollet and Schmitzer, probably of syphilitic origin.

3. Sclerotic Patches and Chronic Interstitial pneumonia. At the root of the lung especially and also extending throughout the tissues are long strands of fibrous tissue mapping out the lobules. This is called the pneumolobulation of Virchow. There may be bronchiectasis or cavity formation. This condition often occurs associated with gummata.

Osler describes a few autopsies in cases in which syphilitic conditions of the lungs were found, which will merit mention. One, on a patient dying of interstitial nephritis, showed the pneumolobulations of Virchow, although very few pulmonary signs had been noticed during life.

In another, the initial symptoms were cough, dyspnea, and hemoptysis, and had been treated as tuberculous in the out-patient department. There were weakness and wasting of the left arm; impaired resonance and numerous râles at the left apex and the base of the right lung were the only physical signs. The patient died suddenly of pulmonary hemorrhage.

The examination disclosed the apex of the left lung consolidated, and section showed a caseous mass surrounded by scar tissue. In the right lung there were many caseous masses surrounded by fibrous bands. In the center there was a cavity, not bronchiectatic, which was filled with blood, and opened into a bronchus and also into a branch of the pulmonary artery.

Fowler and Goodlee state that gummata occur mostly in the lower lobes, often near the root of the lung, and more often in the substance than on the surface.

They have found pulmonary gummata to be of a gray color, presenting a smooth appearance, later becoming of a yellow color, firm and dry. The contents may be discharged, but they have found this to be rare in comparison with the occurrence of similar change in tuberculous masses. They have found them to tend, not like skin gummata, to necrosis, but rather toward scar tissue transformation, with puckering of the lung and pleura. They may become calcareous. Robinson reports an autopsy on a patient who died, showing symptoms of severe thoracic pain on the right side of the sternum, cyanosis, anasarca, and dyspnea. The lungs were found collapsed, airless, no crepitation, with five areas of consolidation, which were dry, airless, and of a grayish color containing yellow patches of firm consistence. No fluid was present. Elsewhere the lungs were slightly moist and crepitant and the bronchial mucous membrane was pale and smooth. The anatomical diagnosis was multiple gummata of the lungs based on a composite picture of gross and microscopical findings, together with: (1) Multiple nodules in middle and lower parts of the lungs, with apex uninvolved; (2) acute internal lesions of vessels within these nodules, and absence of tubercle bacilli; (3) syphilitic aortitis and aneurysm.

Councilman has made exhaustive microscopical studies of the syphilitic lung processes. He has found the essential process to be the production of gummata, together with pneumonitis and fibrinous exudation, also a fibrous change in the alveolar walls, the whole subsequently undergoing caseation.

The first step in the process of caseation is hyaline degeneration of the capillaries of the affected area, then atrophy of the alveolar walls. The alveoli become distended with large pale epithelial cells and the fibrin cells undergo hyaline degeneration. The capillaries are converted into rigid tubes and the lumen is much reduced. Similar changes occur in the small vessels. Around the bronchi and arteries is a formation of connective tissue, the alveolar walls become thickened. The whole then undergo necrosis and a caseous looking mass results. Giant cells, according to Fowler and Goodlee, are not so commonly found as in tuberculosis.

Symptomatology.—According to Osler the symptoms are uncertain. Practically they are those of tuberculosis, but with the physical signs more commonly at the root of the lung and toward the base and nearly always absent in the apices. The clinical features are those of chronic bronchiectasis or fibroid phthisis. With tracheal or bronchial stenosis dyspnea is a very prominent feature.

Fowler and Goodlee describe the following train of symptoms in these cases: Cough. The earliest and most prominent symptom and due to changes in the lung itself. Dyspnea varying in severity. Hemoptysis is not of especially frequent occurrence, but may prove fatal. Expectoration of a profuse, purulent, and offensive nature. Fetid odor is common in advanced cases in this disease. No tubercle bacilli are found on repeated examinations. Pain is not a prominent feature. Emaciation is not so extreme as in tuberculosis. Night sweats are often present. Pyrexia may be considerable or may be absent. The physical signs are those of consolidation and excavation, as determined in the usual way. In this connection it is interesting to note the case reported by Teuxara of Lisbon, Portugal, of what seemed to be ordinary bronchial asthma, with gray and thick sputum. The case was diagnosed as syphilitic on account of the coexistence of ulcers on the leg. Under syphilitic treatment the condition entirely disappeared.

Diagnosis.—Fowler says that in suspected cases we must show: (1) Undoubted evidence of a syphilitic infection. Of course this would now include a Wassermann in suspected cases; (2) Absence of tubercle bacilli from the sputum on repeated examinations; (3) Presence of syphilitic tertiary manifestations in other organs, especially in the viscera.

Stanley, writing in the *British Medical Journal*,

states in regard to the differential diagnosis from tuberculosis that the signs and symptoms must be most carefully analyzed. Hemoptysis, according to him, which occurs with syphilis of the lung, suggests a slow ulceration of a mucous surface and lasts for several weeks. Cough is irregular and may be paroxysmal. Pyrexia, wasting, and sweating may at times occur. He states that the rapid disappearance of these symptoms under antisyphilitic treatment is characteristic and striking. The physical signs in syphilis of the lung are more irregular. His observations have been that the disease occurs in the intrascapular region, especially on the right side, although sometimes it is not confined to the base or central part, and it even may be scattered.

He considers a diagnosis of syphilis of the lung justified with the above symptoms and signs, especially with the history from infection, the occurrence of other visceral lesions, and the absence of tubercle bacilli on repeated examinations. Coexistence with tuberculosis is possible and a lung with beginning syphilitic lesions is probably more susceptible to tuberculosis. Stanley states that early recognition of this syphilitic affection and its appropriate treatment may avoid this later complication. The commencement of a tuberculous process in syphilitics should be the indication for the beginning of a vigorous antisyphilitic treatment.

It also may be noted (Fowler and Goodlee) in this connection that (1) Syphilis affects the base or central part, while tuberculosis affects the apices mostly; (2) Both undergo caseation, but tubercles break down more frequently than gummata; (3) In advanced cases there is often stenosis of the trachea or bronchi in syphilis, while this is absent in tuberculosis.

Prognosis.—In the earlier stages great improvement may be effected by proper antisyphilitic treatment, but after stenosis and dilatation, fibrosis, excavation, and permanent changes of this character have occurred, it is not to be expected that they will disappear.

Treatment.—Most of the older authors pinned their faith on the mercury and iodide treatment and had some measure of success. My own case showed a very good improvement on sodium cacodylate treatment, as mentioned before. I believe that salvarsan in these cases would be indicated, unless the patient were in an extremely weak physical condition, when it would seem that some other means might be preferable.

Conclusions.—1. Syphilis of the lung, while a rare condition, does occasionally occur.

2. All cases of suspicious lung involvements, especially those resembling tuberculosis, and repeatedly showing absence of tubercle bacilli on careful microscopical examinations, should be regarded as possibly syphilitic.

3. Especial care should be taken in cases showing the above mentioned signs and in which no physical findings occur in the apex, but only the base of the lungs. These cases should be regarded as sphilitic.

4. In cases in which syphilis is suspected treatment should always be instituted at the earliest possible moment in order to prevent the permanent changes of fibrosis and stenosis of the bronchi.

5. In a known syphilitic, who is also known by microscopical examination to be afflicted with tuberculosis, I believe it always advisable to administer some appropriate form of antisyphilitic treatment along with the treatment for the other condition.

THE MATERNAL INSTINCT A FACTOR IN THE PRENATAL DEVELOPMENT OF THE EPILEPTIC TYPE OF NERVOUS CONSTITUTION.

By RUSSELL G. MacROBERT, M.D.,

NEW YORK.

RESIDENT PHYSICIAN, SECOND DIVISION, NEUROLOGICAL INSTITUTE.

Although the epileptic type of nervous constitution[1] is fully determined before birth, the direct inheritance of epileptic attacks in the children of epileptic parents is rare (17 cases in 2000, Starr[2]). Neuropathic stock predisposes only in a general way. Cousins are more frequently affected than brothers or sisters. Specific factors must determine the epileptic child of the family which did not enter into the development of his non-epileptic brother or sister who may however reflect the general neurotic heredity in various other ways, as in hysteria, neurasthenia, psychasthenia, or tic.

The epileptic occurs with a frequency not generally suspected. There is one pronounced epileptic for every 400 of our population (Church and Peterson[3]) but many are known only to their families. No race under the sun escapes. The specific factors that determine their development are therefore of a fairly frequent and ordinary nature.

The absence of all pathognomic physical signs of epilepsy should earlier have directed our search more confidently towards a psychogenic origin of this disease. Gowers,[4] from a consideration of the pathological anatomy of epilepsy, made statements as far back as 1888, which implied the prediction that our explanation of epilepsy must come from the realms of psychic occurrences, whose only changes are of a functional nature. Some of his words in speaking of this point are "The changes in the nerve centers are probably of that fine kind which is revealed only by altered function and eludes the most minute search."

The epileptic manifestations are reactions to disturbances in the psychic sphere where our instincts and emotions have their foundation and play. Stoddard[5] of London in 1909 summed up some existing views by writing, "Broadly expressed, one would say that the essential feature of the epileptic is that there is a periodic loss of volitional control of the instincts and emotions." He quotes Aschaffenburg as asserting that, "The specific feature of the epileptic character is a periodic fluctuation of the affective tone." The most prominent abiding features of the epileptic personality are exaggerations and discrepancies in his emotional domain. His manifestations probably result from an imperfectly developed instinct.

The essential motive in all genuine epileptic fits is believed by Clark[5] to be an unconscious striving on the part of the epileptic to return to intrauterine life. Hoch and others say that this motive has to be accepted. My study urged consideration of this view.

The epileptic feels better after a fit. Peace is restored to a restless subconscious or, as Stoddard says, the fit seems to "clear the air." To the subconscious motive or desire of the epileptic the fit serves a purpose and has a significance. Such a subconscious desire in the epileptic appears to be instinctive. The instinct is a perverted one for it directs a return to intrauterine life, which may be interpreted as a desire of the epileptic not to be in or of the world. His return is represented periodically by the epileptic manifestations and therefore is gratifying to his unconscious desire. As this desire never could have been in the consciousness of the epileptic it was regarded as one not essentially of his own making, and my investigation as to its cause was therefore directed to the parents of epileptic children.

The nervous state of a pregnant woman is a matter of material significance to the makeup of her child's nervous constitution. Dana,[6] in speaking of the etiology of epilepsy, says that "Powerful emotions during pregnancy have some influence." It seemed worth while, therefore, to determine whether or not some particular emotional factor or imperfect instinct could be uncovered that acting during pregnancy influences the nervous anlage of the developing child and is responsible for the deformed or dwarfed emotional and instinct equipment that prompts the strange expressions of the epileptic constitution.

A case of pure psychogenic convulsions studied with Dr. Ames and reported at the Neurological Section of the Academy of Medicine in December, 1914, taught several lessons confirmatory of Clark's hypothesis and instructive to further advance.

The patient was a girl 18 years of age who entered the Neurological Institute November, 1914. She had been subjected for four years to violent one-sided convulsive seizures occurring periodically like those of the epileptic and continuing till complete exhaustion set in. There was absence of hysterical stigmata but the condition responded to psychoanalysis. For details the reader is referred to the publication of this case in the MEDICAL RECORD[7], but instructive points were brought out by the psychoanalysis of this convulsion which can be enumerated as follows: (1) The convulsion was identified as a reestablished behavior phenomenon. (2) The reestablisment of this behavior was unconsciously desired for it served a perverted instinct. (3) The behavior represented that of a time only a few years earlier in the patient's life. (4) A revelation of the desire was appreciated by the patient. (5) When the desire was recognized and relinquished, its fulfillment, the convulsive attacks did not reappear.

A psychogenic origin of the epileptic should, apart from the first point agreeing with Clark's hypothesis, agree in a measure by its other points with those of this psychogenic convulsion. It is Clark's idea that the epileptic fit is the reestablishment in a violent form of the movements of a child in utero and has the accompanying unconscious state of that time. The simple loss of consciousness of a petit mal attack is a less energetic attempt at the same performance. To me it seems positive that something must happen during the unconscious spell that is gratifying to the unconscious motive but which the conscious mind would not approve or tolerate. Unconsciousness and amnesia allow this performance to continue unchecked.

The epileptic type of nervous constitution would seem then one possessed of a perverted instinct that desires the fit, thereby agreeing with the second point. The third point also would be fulfilled if we wish to regard the intrauterine life as the time of the epileptic's life represented by his fit. The last two points indicate that if the nature of this instinct could be revealed to the epileptic and he could perceive it with his conscious reasoning faculties as a subconscious desire for his convulsions this desire could be relinquished and its consequences would cease.

Among my patients during the past few months at the Neurological Institute an interesting fact was revealed. The epileptic was repeatedly found to be the child that before birth was most fervently unwelcome. He was the child that during this early developmental period was deprived of a proper emotional and instinct endowment. In some instances the attitude of the mother is not merely a lack of welcome but a mental rebellion and a hate for her unborn offspring. The measure in which this factor is present during pregnancy and the associated measure of fright, grief, worry, chagrin, mental or moral strain or shock, the common starting points of psychogenic disease, aggravated, of course, by neurotic heredity seem to determine the strength of the peculiar characteristic tendencies that are imparted to and decide the epileptic type of nervous constitution.

Sometimes the maternal instinct in the mother seemed quite lacking but often there was probably only a temporary perversion of this instinct. In some families of several children there was only one pregnancy which was unwelcome and this turned out to be the epileptic child. A defectively developed instinct seems to be contending with the epileptic from birth. Constantly struggling with this defective instinct he goes down before it at times of instability of his nervous organization, in early life and adolescence easily, but if then escaping succumbs at times when his nervous system is racked by a nervous strain, by some disturbing psychic experience or by the continual irritation of a pathological brain condition or other organic trouble.

"The rise of the egoistic sentiments and decline of altruistic" in the epileptic indicate only a natural striving for balance, or struggling compensations by his conserving forces for the defect in him of instincts, advantageous to his fellowman. He feels the extra need to think only of himself.

Epilepsy is not, properly speaking, directly heritable. The neurotic element supplied by heredity would seem to play only a general role in conditioning an unnatural feeling of the mother toward her unborn child. Chance existing reasons of environment or circumstance play also their important part at times in such an attitude of mind. It is readily understood why neurotic stock should by affecting instincts play its part in this cause for the development of the epileptic.

Such an explanation makes it clear why the epileptic is common to all races, all ages and in the frequency that exists, his determining characteristics being the result of a psychic state possible to any woman bearing a child and needing no other

specific complement than could be supplied by her own distorted thoughts, emotions, instincts, and desires.

The very interesting views of Freud and the other leaders of the new psychology trace all manifestations of hysteria to mental processes more or less morbid, in which motives of shame have resulted in repressing the consciousness of certain experiences which thus become unconscious or subconscious. In this state they tend to symbolize themselves and hysterical manifestations arise. In the case of the epileptic the morbid mental process of the mother must work its disturbing effect by influencing the instinct makeup of the child with which she is pregnant.

The subconscious desire or instinct that prompts the convulsion can be regarded as a psychophysiological system which becomes dissociated. The dissociated system present in the subconscious and coming to the upper strata of consciousness becomes manifested with a very intense sensorimotor energy. It manifests by liberating all the energy it possesses until fatigue and exhaustion set in. Sidis[9] compares the liberation of a dissociated system with its overwhelming energy to the eruption of an underground volcano, this liberation giving rise to temporary attacks or seizures by subconscious states of the whole field of upper consciousness. He says that understanding the energy which the dissociated subconscious system manifests in this way is not surprising that it appears almost supernatural and by the superstitious ascribed to diabolical possessions. Impulsive insanities and psychic epilepsy are recognized already as really being due to this mechanism.

A quotation from Sidis in speaking of the threshold and mental systems shows the way to control an undesired subconscious system. "Dissociated systems present impulsiveness, because of lack of associated counteracting systems. The only way to diminish the overpowering inpulsiveness with which the dissociated subconscious systems make an onset in their rush into the personal consciousness is to bring about an association with counterbalancing or inhibitory controlling conscious systems, to work the dissociated system into the tissue of the personal, controlling consciousness." When a system is thus brought into consciousness or the whole situation perceived by the patient the seizure vanishes completely.

At the present writing it seems that the manifestations of the epileptic result from the promptings of an instinctive and unconscious wish. This fact would place the epileptic in almost the same category as the hysteric whose manifestations, whether they be paralysis, blindness, or convulsions, are admittedly prompted by an unconscious wish. Psychological treatment of the epileptic seems strongly indicated.

THE SUSTAINED FAILURE IN THE PROBLEM OF TUBERCULOSIS.

BY MARY E. LAPHAM, M.D.,

HIGHLANDS, N. C.

PHYSICIAN HIGHLANDS CAMP SANATORIUM.

"NOTWITHSTANDING the immense sums expended, it is doubtful whether we are getting our money's worth in lowered death rate, which is, after all, the final criterion by which the success or failure of the anti-tuberculosis campaign must be determined." The above is quoted from an editorial of March 6, 1915, in the *Journal of the American Medical Association*, entitled "The Sustained Interest in the Problem of Tuberculosis." Paraphrasing the above, I should say: Notwithstanding the immense sums expended, it is certain that we are *not* getting our money's worth in lowered death rate, which is, after all, not the final criterion by which the success or failure of the anti-tuberculosis campaign, must be determined, since the reduction of the death rate has been obtained entirely by curing the victims of the disease by improved methods of treatment and not by actually reducing the number of manifest cases.

Landis says: "We cannot prevent a disease by curing its victims," but the lowered death rate from tuberculosis has so far tended toward persuading us to believe that we can. It is true that we have cut the death rate in half, but, in our satisfaction we overlook the fact that the number of cases is constantly increasing.

Ten years of hard work, two hundred millions of dollars, and still in no place in the world has this disease been reduced in numbers. Still the cry is for more beds, more hospitals, more milk and eggs, more nurses, and more money. Governor Craig, in his annual message, estimates that the entire revenue of the State of North Carolina would be insufficient to care for all its tuberculous victims in sanatoriums.

If our efforts for the past ten years were really successful, if instead of merely palliating we had really prevented, there should be less need for help instead of more; our hospitals should have fewer beds for tuberculosis patients and the number of cases should be markedly decreasing. Where is the fault? Are the fundamental ideas governing our campaign inadequate?

Tuberculosis is still costing the United States over nine hundred million dollars a year. Does this look like success? Is it not time to question our theories and see if they suffice?

What are these theories? First, we believe that we can protect our people against tuberculosis by protecting them against infection. Second, that we can prevent infection by isolating open cases and by promoting their recovery. Can we protect our people against infection? If so, we must begin with the children, for by the time they reach maturity, they are all infected. Studies of infants six weeks old, with not a trace of tuberculous lesions, show the presence of tubercle bacilli and these

studies teach us that non-tuberculous babes, of non-tuberculous parents, in non-tuberculous homes, have tubercle bacilli resident within their bodies just as they have colon bacilli. What is the source of these infections? Open cases, we answer, with the promptness and courage characteristic of ignorance. Is this true? Is it likely that every child has been exposed directly or indirectly to contagion from open cases? And, if so, is it probable that we can prevent it? Is the tak of safeguarding every moment of the lives of twenty million school children for this year and all the years to come, a practical undertaking? Certainly not, therefore we must gather in the open cases so that they cannot infect our children. But suppose open cases are not the sole source of danger? Suppose there are other sources, at present unknown and undreamed of, against which we are powerless to contend. Suppose open cases are an infinitesimal source of supply compared with the universality of the infections. Hillenberg found that from 25 to 70 per cent. of all the children in an exceedingly healthy hill district were infected with tubercle bacilli, although there had not been a case of tuberculosis in that district for ten years and the disease was almost unknown. Open cases could not have been the source of these infections, what was? If the entrance of tubercle bacilli into the bodies of children is a natural and inevitable phenomenon, then their safety can never be secured by attempts to protect them against an infection which has already occurred. Safety does not lie that way, but must be sought in preventing the consequences of these infections. The entrance of tubercle bacilli into the bodies of our children is inevitable and their residence is constant and can never be prevented, neither now nor in all the years to come. This menace to the health of our nation will always exist and the problem is not how to prevent infection, but how to prevent the development of tuberculous processes. We can only deal with the consequences of these infections since we can never prevent them. How can we prevent these infections from becoming dangerous by developing into tuberculous processes?

Our social workers will see that sanitary, housing, labor, moral and political problems are solved. All good is against their development, all bad favors it, but the best conditions of existence do not suffice for adequate protection. Nothing does and nothing can. In spite of the best of life, tuberculous processes will constantly and hourly develop with us even as they do with the lower animals, who are ideally protected. We cannot prevent infections, and we cannot prevent their development, but we can realize that the greatest danger from tuberculous processes is their lack of manifestations and that, in order to detect them at the earliest possible moment, we must not wait for them to thrust themselves upon us but periodically do the best we can to determine their presence or absence. Instead of waiting for a case to become manifest, we should regard the loss of lung substance sufficient to cause manifestations as evidence of neglect or incompetency. Let us change from attempting to prevent infections to attempting to prevent structural changes sufficient to cause manifestations. Since each child is menaced, each child should be watched. Our present methods depend upon manifestations. No manifestations, no examinations. This is all wrong, because the apparently healthy child may be in equally great or even greater danger than his sickly brother. The "pretuberculous" child, the child that is "tuberculizable," the child offering any suggestions of ill health, will in the future be safe from tuberculous processes because our perceptions of these dangers will be so quickened, our comprehension so enlarged that we shall work with immense precision to detect and weed out these threatened ones. As soon as the profession as a whole comprehends the real nature of tuberculous processes and their diagnosis by negative findings, the suggestive children will be saved, but the crops of consumptives for the years to come, for 1920 and 1930 and on all through life, are being silently prepared to-day among apparently perfectly well children. Children below par will attract attention and their tuberculous beginnings will be discovered and overcome so that they will not furnish the cases of the future. Tuberculous processes are, and must always be, perpetuated in well children and adults, because good health is requisite for concealing their development.

When the health of the child is not sufficiently affected to attract attention, the danger is masked, screened, and concealed until it is ready to strike. Each child is exposed to this danger. Tuberculous processes may develop any day in any child, not because of exposure to open cases, but because this constant residence of tubercle bacilli is a perpetual, potential source of danger from within. The only way to reduce the number of manifest cases of tuberculosis is to not permit them to become manifest. To seek and find and overcome. The world of well children and adults must be explored and the lurking dangers exposed before we can protect the future of our people and this can best be done by competent periodical examinations of our school children. New York City is spending two million dollars a year in its tuberculosis work and getting no results in reducing the number of its cases. The problem becomes more vast each year and the expenses more impossible. Suppose a study could be made of the pupils in one public school in one of our large cities. If five hundred of the children in one school could be regularly examined by an enthusiastic expert for five or ten years, what would it cost and what would be gained?

It would cost for an enthusiastic expert for

one year	$2,500
For *x*-ray and laboratory work	2,000
For incidentals, office expenses, etc	500
Total	$5,000

What should we gain? Beginning with the fall of 1915, all the children threatened with tuberculous processes among these five hundred would be weeded out, fed, put in open-air schools and protected. Henceforth, these children would teach us the efficacy or failure of arresting tuberculous processes at the earliest possible moment. The records would inform us of the percentage of manifest cases later on. Suppose these cases remained well, should we have reduced the future crop? Would this be the first success in lessening the number of manifest cases? By keeping track of our work for five or ten years we should have a sustained, comparative study of tuberculous processes in well children which would furnish an immense amount of comprehension as to their nature and the problem of the tuberculosis of adults might be solved at the same time. Which is more important, the reduction of the death rate or the reduction of the number of cases?

SOME INTERESTING PHENOMENA ASSOCIATED WITH MIGRAINE.

MIGRAINE is a frequent and interesting disease, and much has been written by various authors in the past concerning its possible relationship to epilepsy, in which it has practically been proved that clinically migraine and epilepsy are first cousins. But there are many neglected phases of this condition which are surely deserving of wider recognition than they have as yet received. And in a disease which is of such great frequency as hemicrania, this information should be further popularized. In most cases of migraine the manifestations consist of nothing more than recurring periodic headache of a varying degree of severity, often associated with gastric distress, blurring of vision, and scotomata, frequently colored. But we know that in some cases we also find that hemianopsia, hemiparesis, hemiparesthesia, astereognosis, hemiplegia, anesthesia in the distribution of the fifth nerve, ophthalmoplegia, recurrent facial palsy, aphasia, and even mental disturbances may accompany and exist as sequelæ of the migrainous attack. In the great majority of cases these phenomena of a focal nature are transitory, and it is believed that they are due to temporary vascular spasm, a theory which is supported by the clinical history of such cases.

Now, although migraine is as a rule harmless, J. Ramsey Hunt of New York has recently pointed out (*American Journal of the Medical Sciences*, September, 1915) that paralytic and other persistent sequelæ of migraine also occur. These permanent focal symptoms are rare, but they may be very serious. They include facial palsy, ophthalmoplegia, organic hemiplegia with aphasia, hemianopsia, and optic atrophy. Before becoming permanent, as sometimes rarely occurs, these symptoms reappear in recurrent attacks, each of which is transitory, but at times becoming more and more prolonged until finally a permanent attack may ensue. It is evident that these atacks must have some pathological basis, which probably is essentially a vascular spasm. Nor must it be forgotten that vascular accidents, such as hemorrhage and thrombosis, are much more liable to occur in one who, in addition to his migraine paroxysms, is suffering from some degree of cerebral arteriosclerosis, than in one whose cerebral blood-vessels are perfectly normal.

In order to make a diagnosis of persistent and other permanent sequelæ following migraine, or of what may be called migraine paralysis, one must be certain of a definite clinical history of true, essential, or idiopathic migraine, and of the direct relationship of the paralytic condition to the migrainous attack. So-called warning symptoms, consisting of recurrent transient ptosis, diplopia, hemianopsia, hemiparesis, aphasia, and Jackonian seizures are not infrequent. Anatomically there is found a disturbance in the region supplying the area in which function has been lost, the pathological lesion in the permanent paralyses accompanying and following migraine consisting of vascular thrombosis (as a rule) or even of vascular hemorrhage—in other words, vascular lesions of a permanent nature. In all such cases the blood and spinal fluid should be subjected to a complete examination, and syphilis should be excluded as an etiological factor.

THE CURABILITY OF TUBERCULOUS MENINGITIS.

FROM time to time there is reported in medical literature a case of complete recovery from a disease in which the diagnosis of tuberculous meningitis has been established both clinically and bacteriologically. The importance of making a critical analysis of every report of this nature is quite obvious. There can no longer be any question as to the authenticity of many of the cases of recovery from tuberculous meningitis so far recorded. That these cases constitute an almost infinitesimal proportion of the total number of cases of this disease must be admitted, but they provide the one bright ray of hope in stimulating whatever therapeutic efforts may be at the disposal of the practitioner.

An example of the few cases referred to above is perceived in the case reported by Ferdinando Fonzo in *La Pediatria*, May, 1915. The patient was a girl eleven years of age belonging to a tuberculous family, who for a year and a half prior to the illness for which she came under observation had suffered frequently from an irregularly remittent fever with occasional chills. The patient was first seen by the author on the seventh day of an attack that was ushered in by a chill, and that was accompanied by a fever with slight remissions, and during the first few days by a slight cough. On the fifth day of the disease there was first noticed a clouding of consciousness, and there were then manifested involuntary movements of the facial muscles and of the arms and legs, strabismus, and seizures of vomiting. Physical examination revealed the characteristic objective signs of meningitis. By lumbar puncture there were removed under moderate pressure 40 c.c. of a limpid cerebrospinal fluid, in which there formed on standing a fibrinous reticulum, and in which on microscopic examination there were detected the typical acid and alcohol-resisting bacilli of Koch. Following the

performance of lumbar puncture the general condition of the patient improved, at the end of six days the sensorium was apparently normal, and fifteen days after the beginning of the illness the patient was regarded as clinically cured.

There can be little doubt that the above case was one of tuberculous meningitis. Fonzo interprets the initial symptoms as the expression of an influenzal infection in a patient harboring a latent tuberculosis. This period of latency would correspond to the first stage in Hamburger's classification, in which stage there are healed or latent lesions in the lungs or tracheobronchial lymph nodes. The second stage is characterized by the diffusion of the infection from these lymph nodes throughout the entire body, and the third stage by the development of ulcerative lesions in the lungs. According to this conception tuberculous meningitis would represent the transition from the first to the second stage. This transition, initiated by whatever cause, whether traumatic or infectious, breaks down the barrier of defence during the first stage. In the case reported by him Fonzo believes that an attack of influenza precipitated the general diffusion of the tuberculous infection.

THE TEACHING FUNCTIONS OF BOARDS OF HEALTH.

In recent years there has been a great increase of State and city health department pamphlets intended for the information of the public. It is encouraging to note that President-emeritus Eliot of Harvard University is a strong advocate of such work. He says that there is nobody to give Americans the sort of instruction they need about tuberculosis, alcoholism, venereal diseases, prostitution and diet, and to give it with authority, except the medical profession and the public health officials (*American Journal of Public Health or Social Hygiene*, September, 1915). This statement is well substantiated by the fact that tuberculosis continues to spread—thus showing that public opinion has not forced adequate control of this disease, although its infectiousness has been known and widely taught for a generation past. In regard to alcoholism it has not been brought home to the entire population that the habitual use and above all the abuse of alcoholic beverages reduces the productiove efficiency of the community. There is great room for improvement over the present ignorant way of dealing with habitual drunkards.

Public neglect and silence about venereal diseases are no longer justifiable, since recent discoveries have made the diagnosis more certain, and the treatment more effective. Interest should be quite as strong in these as in any other communicable diseases. The proper handling of venereal diseases by the public naturally leads to the question of how the public should treat prostitution. "Recent inquiries have demonstrated that more than half of the prostitutes in a modern city, or a rural community, are likely to be feeble-minded women." The public needs to be aroused on this subject. The remedies usually suggested, namely, license, regulation, and segregation, have failed in Europe and in Asia. It is essential that true information on this subject be given to the public.

"The ignorance of the American people concerning individual, family, and public hygiene is vast; and its consequences are deeply to be deplored. . . . The ignorance of the American people concerning the enjoyable, healthful, and productive use of foods is profound; and this ignorance results in immense waste, reduced industrial efficiency, unnecessary ill-health, and shortened life." The ordinary American eats too much protein. It is a proper function of health authorities to instruct the public on the nutritive values of various foods as well as to protect it against unsafe food.

President Eliot has rightly called attention to the need of more well-informed zeal on the part of all persons, if the power of preventive medicine to promote the public welfare is to be fully utilized.

BLEEDING FOR MADNESS.

The sanguinary old days when venesection was a panacea are to us now nothing but a curious history and while there are certain selected cases in which venous engorgement is a prominent feature and phlebotomy is indicated, still the physician who would travel around nowadays with lancet and basin, bleeding as he went, might be likely to find himself regarded as an anachronistic lunatic who were better behind bars. We are most of us familiar with the brief but bloody career of Gil Blas as a surgeon. Following the ingeniously simple therapy of his master he bled them and purged them and finally turned them over to the sexton.

After the ingenious psychology of the psychoanalytic school, the elaborate researches of what might be called the physicochemical school, and the meticulous theorizing of the endocrinous school, it must be quite refreshing for the alienists to turn to the simple little remedy for melancholia set forth by Dr. F. Lucas Benham in the *Lancet* for September 4. Benham would let out about a pint or so of the bad blood which is doing all the mischief and thus relieve the pressure on the brain. He says, "in meeting with a case of melancholia, especially one of rapid onset, where the brain is evidently oppressed and clouded and working with considerable friction, the practitioner's clinical instinct will suggest the employment of an efficient sedative which will enable the machine to run with more ease and less pressure." He hints that the prompt application of a little, sharp scalpel may prevent a suicide or a life-long incarceration in a madhouse. He tells of a young Englishman who came to him in Australia in a state of depression and was promptly relieved of about twenty ounces of blood. The young man was thus enabled to get rid of his ideas of suicide and wrote his physician later that he had entirely recovered and had enlisted and gone to the front. The question naturally obtrudes itself whether or not this is a form of suicide.

The writer recommends the more general adoption of venesection in depressed cases, but we cannot help feeling that this advice is based upon a too naive conception of mental disorder. To be sure, there may be cases of high blood pressure

where the symptoms would be relieved by a judicious phlebotomy, but it seems that the criterion should be that furnished by the sphygmograph and not a fanciful and obsolescent concept of mental disorder.

WHERE MEDICINE AND PEDAGOGY TOUCH.

MEDICINE is quite as much concerned with the prevention of disease, or the preservation of health, as with the cure of disease. Although the majority of the medical profession has been kept so busy with the alleviation of suffering that it has had very little opportunity to work actively in this field, it has never been conscious of any loss of interest. In fact, every physician feels that he is quite as much concerned with the preservation of health as with the treatment of patients. This feeling is inspired by the unwritten ideal of the medical profession which includes the prevention of disease.

Education is concerned with the perfect healthy development of both mind and body. The teaching profession is more fortunate than the medical profession in having a definite motto. This motto is "A sound mind in a sound body" and was given to it by the great educational theorist, John Locke. Everything that in any way bears either directly or indirectly upon the development of a healthy perfect mind is of great importance to the teacher. It should be no less so to the physician. It is here that the professions of teacher and of physician touch common ground in the realm of ideals. As a matter of fact the medical profession has not until recently been concerned with child psychology or the proper and healthful training of the mind. It is a field of science that has developed aside from medicine. Really the ideal of the teacher is so all-inclusive as to embrace medicine, especially preventive medicine. Or, to put it another way, we might say that the ideal is so broad that it really expresses the ideal of medicine. The motto, "A sound mind in a sound body," could serve for the medical profession quite as well as for the teaching profession, and medicine would be richer for having its aim so clearly stated.

If the teaching profession should charge us with over-reaching, we could remind it that its leader, John Locke, was a physician, and that it was with the insight he gained as a physician that he saw and expressed so clearly the ideal of the teacher, "A sound mind in a sound body." This is the ultimate aim of all medicine.

DOCTORS AS WAR PRISONERS.

THE articles of the Geneva Convention, adopted July 5, 1906, provide among other things that the belligerent who is forced to leave the sick and wounded in the hands of the enemy must also leave a certain proportion of medical attendants and equipment and that members of the Army Medical Service who have fallen into the hands of the enemy must continue their duties, but as soon as their service can be dispensed with, they must be sent back. Just how closely the provisions of these articles are being observed by the present combatants is, of course, impossible to ascertain although we hear complaints from both sides of violations of them. The German side of the question is voiced by the editor of the *Deutsche medizinische Wochenschrift* in his issue for June 17, who after calling attention to the above articles, complains that Germany is getting the worst of the bargain. He says that his nation has over 800,000 prisoners and has not nearly enough of the enemy's physicians to care for them so that an unjust tax is levied on its own military surgeons. He alleges that Russia has without exception retained every German surgeon captured although they have not sufficient German prisoners in that country to justify this. Speaking of the large number of Russian prisoners he states that it is particularly necessary to have Russian physicians to take care of them, partly because their knowledge of the language would facilitate their care and allow each doctor to do a good deal more work than is the case when interpreters are necessary and partly because the Russian is racially less susceptible to certain contagious diseases such as typhus than the German. Dr. Schwalbe, the editor of the journal mentioned, is, however, rabid in his hatred of everyone, belligerent and neutral alike, who does not subscribe in toto to the German views; in short, he is ineligible to membership in Dr. Meltzer's Medical Brotherhood, and consequently his testimony against the Russians is not to be accepted without corroboration from some more pacific source.

LUMBAR PUNCTURE FOR THE ENDOCRANIAL SYMPTOMS OF TYPHOID FEVER.

THE phenomena indicative of cerebral irritation seen in the early days of typhoid fever, such as headache, mental confusion, delirium, etc., constitute one of the most unpleasant features of this affection, since the patient must be constantly watched, and young, vigorous subjects often do violence to themselves. As a rule we have to depend on measures which reduce the fever, such as cold applications, for combating this condition. At a military medical evening held last March in Metz (*Deutsche medizinische Wochenschrift*, June 2) Schemensky reported excellent results from lumbar puncture in these cases. He had attributed the symptoms in part to increased intracranial tension, and the results of puncture showed this to be true for a large majority of the cases. Three patients with severe headache were completely relieved and of fifteen punctured for disturbances of consciousness nine were benefited. The six who did not improve had severe pulmonary or cardiac symptoms.

WAR AND ANTHROPOLOGY.

WHENEVER many varieties of mankind are brought together the local anthropologists, ethnologists, and philologists are usually found employing their gratuitous opportunities for study. This has been seen especially in world expositions. While warfare does not necessarily entail similar opportunities, the present struggle in Europe has given this chance, especially to the German scientists because of the motley character of the prisoners in the detention camps. Thus Buschan in a communication to the *Deutsche medizinische Wochenschrift* for June 24 improved a leave of absence by studying anthropologically seventy-five men selected from the following races: Caucasians (four different peoples), Koreans, Tartars, Letts, Esthonians, Basques, Bretons and Welsh. It was found that anthropological data of the Germans were defective for pur-

poses of comparison, and the author thus subjected numerous young German recruits to the same examination for control purposes. He believes that the government should request its medical men to make a mass investigation along the same lines.

News of the Week.

Casualties in the German Medical Corps.—The *Deutsche militärärztliche Zeitschrift* publishes the following report of casualties in the medical corps of the German army and navy for the first thirteen months of the war: Wounded, 437; missing, 125; captured, 95; killed, 119; died of wounds, 45; died of disease, 98; killed by accident, 20.

Dr. David Wheeler of Boston, formerly attached to the American Ambulance and more recently a belligerent in the Foreign Legions of the French army, was severely wounded in the battle of Champagne. A number of other Americans were wounded and thirteen killed in the same action.

Work of the American Ambulance.—During the first eleven months of its establishment the field service of the American Ambulance in Paris has transported 57,000 wounded from the front. The number of automobiles now engaged in this service is about 90, with 20 more machines attached to the hospital at Neuilly. The cost per trip per wounded man runs from 10 cents to 60 cents, depending on the length of the run and the condition of the roads. One supply and one staff machine accompany each of the units in the field, themselves composed of from ten to twenty-five cars. There have been no deaths among the drivers of the field ambulance, although they penetrate very near to the lines and are frequently under heavy fire. Additional cars are added to the field equipment as the fund grows. The number of beds in the hospital at Neuilly has increased from 175 to 600. The per diem cost is $1.32 for each patient, which is not considered high, regard being had to the increased cost of all necessities and to the fact that all the patients are surgical.

Typhus in Serbia.—Dr. R. P. Strong of Harvard, who recently returned from Serbia, where he was in charge of the American expedition fighting the typhus epidemic, is quoted as saying that the total number of deaths from tphus in Servia had been between 130,000 and 150,000. Practically every district was visited by the Commission's agents, who distributed supplies of medicines and disinfectants and instructed the inhabitants in preventive methods. Plants for the manufacture of medical supplies have been established in all the large cities. The work of educating the people in cleanliness and disease preventive methods was enormous, but it has been successful, and as a result conditions are in fine shape and there is virtually no chance of a return to former chaotic conditions.

Red Cross Nurses Killed.—The Russian Red Cross has published a list of forty-six Sisters of Mercy who are alleged to have been killed during Austro-German bombardment of Russian hospitals.

American Missionaries Expelled from Van.—Sixteen American missionaries from Van, Turkey, arrived in New York last week, after a long and perilous journey through the Caucasus and Russia. Among them were Drs. Clarence Ussher and George Reynolds. They report that the Turks, under the command of a European officer, bombarded the mission buildings, which were at the time flying the Red Cross and five United States flags.

New York City Death Rate.—During the week ending October 2 there were 1,209 deaths in this city with a rate of 10.36, as compared with 1,132 deaths and a rate of 10.58 for the corresponding week of 1914. The rate for the first forty weeks of 1915 is 13.37, as compared with a rate of 13.81 for the corresponding period of last year.

For the Improvement of Vital Statistics.—The Washington State Board of Health has given notice that in future it will prosecute all physicians who neglect to report births and deaths and give notification of the occurrence of infectious diseases. Local health officers who fail to placard homes in which cases of infectious disease occur will also be prosecuted.

Hospitals Urged to Hunt for Carriers.—The Health Department of New York has sent a letter to all the hospitals, some 200 in number, in the city urging them to have a physical examination of all the members of their kitchen staffs made periodically. The outbreak of typhoid among the house staff at the Sloane Maternity Hospital caused by the presence of "Typhoid Mary" among the cooks is cited as a justification for such an examination. The department is now conducting such an examination of all cooks and waitresses in the hotels and restaurants of the city.

Tetanus After Vaccination.—Four cases of tetanus in recently vaccinated children have recently occurred in this city. In each case the infection was found to have been carried by dirty dressings applied to an open wound caused by scratching, examination of the virus used having proved it to be free of tetanus germs.

Street Accidents in New York.—During the month of September there were 28 deaths from traffic accidents in this city as compared with 49 deaths from the same cause in September, 1914. Eighteen were killed by automobiles, of whom ten were children under 8 years of age.

National Association for the Study of Pellagra.—The third triennial meeting of this association will be held in Columbia, S. C., on Thursday and Friday, October 21 and 22, 1915. The headquarters will be at the Jefferson Hotel; the scientific meetings will be held at the State Hospital for the Insane. The president is Surgeon C. H. Lavinder, U. S. Public Health Service; the secretary, Dr. J. W. Babcock, Columbia, S. C.

A Radium Institute in New York.—It is reported that a Radium Institute similar to that in London and some other European cities, will be established in this city, through the labors of Dr. C. Everett Field. There will be a hospital for the treatment of cancer and other diseases by the external and internal use of radium, and also laboratories for the study of radium in its many phases. The institute will begin with one gram of medicine, but this amount will be increased later. The founders of the institute are seven in number, but their names and the names of those composing the medical staff are not yet announced. The building will be in the neighborhood of 72d street and West End avenue.

A New Disinfectant.—It is stated that a new disinfectant has been discovered by workers in the laboratory of the Public Health Service in Washington. The *Bulletin* of the P. H. Service describes the substance as follows: "The new preparation is derived from pine oil, a by-product in the manufacture of turpentine. It is easily prepared by mixing

certain proportions of the oil with rosin and sodium hydroxide solution, the finished product being a reddish brown liquid, rather thick and oily in appearance, but free from turbidity. With water it makes a perfectly white emulsion, much resembling milk. It has a pleasing odor, no objectionable taste and attacks neither fabrics nor metals. It possesses over four times the disinfectant properties of carbolic acid and is almost non-toxic, so that it may safely be used as a throat spray or mouth wash in solutions of the ordinary strength. The cost of the preparation is remarkably low, as it can be manufactured for less than 50 cents a gallon, solely from products of this country."

New York and New England Association of Railway Surgeons.—The twenty-fifth annual session of this association will be held at the Hotel Astor, New York, on Thursday and Friday, Oct. 21 and 22, under the presidency of Dr. W. H. Marcy of Buffalo. The corresponding secretary is Dr. George Chaffee, 338 Forty-seventh Street, Brooklyn, N. Y.

Reprints Requested for the Library of the Surgeon-General's Office.—Lt.-Col. McCulloch, librarian of the Surgeon-General's office, writes that in order to make as complete as possible the bibliographies of American physicians in that library it is desired that all reprints and pamphlets not saleable in the general market should be deposited therein. Physicians will therefore confer a benefit by sending copies of all separate pamphlets and reprints of their authorship, or bound collection of the same, to The Librarian, Surgeon-General's Office, Army Medical Museum, Washington, D. C.

New York State Civil Service Examinations will be held in various cities throughout the State on October 30, for the following appointments:

ASSISTANT BACTERIOLOGIST, Quarantine Laboratory, Department of the Health Officer of the Port of New York. Men and women. Salary $1,200 per annum. Open only to candidates who have satisfactorily completed a systematic course in bacteriology and have also had not less than eight months' practical experience in laboratory work, including work in the bacteriology of cholera and plague. Two years' practical work in bacteriology at full time in a laboratory will be accepted as the equivalent of a systematic course in bacteriology. Candidates will be examined on the technical procedures used in the study of the pathogenic bacteria of infectious disease. These positions will require full-time attendance and incumbents will be required to be on call for additional night service should emergencies demand such service. Subjects of examination and relative weights: Written examination on bacteriology as related to quarantinable diseases, 1; education and experience, 1. Open to non-residents as indicated in paragraph 3 above.

ASSISTANT PHYSICIAN, State Charitable and Reformatory Institutions. Men only. Open only to licensed physicians of New York State. At least six months' experience in a general hospital is required. Preferred ages 25 to 40 years. Subjects of examination: Anatomy, physiology, chemistry, materia medica, therapeutics, obstetrics, surgery, theory and practice, 1; experience, 1. Vacancies at $1,200 and maintenance exist at the Hospital for Crippled Children, West Haverstraw, and at the Syracuse Institution for Feeble-Minded Children. For the latter vacancy the requirements are at least one year in a general hospital or an equal period of post-graduate work in a research laboratory.

CORONER'S PHYSICIAN, Albany County. Paid by fees; for each post-mortem examination, $20; for examination of body when post-mortem is unnecessary, $5. Candidates must be legally licensed medical practitioners and residents of Albany County, as above. They will not be required to appear at any place for written examination, but will be rated on their experience and personal qualifications as shown by their sworn statements and by answers to such inquiries as the Commission may direct to proper sources of information among persons acquainted with their experience and qualifications.

SUPERINTENDENT, Fulton County Tuberculosis Hospital, salary $750, without maintenance. The superintendent will be required to visit the hospital three or four times a week and oftener when necessary, the hospital being under the immediate charge of a woman as head nurse. Open only to men, who have been at least for three months immediately preceding the examination residents of New York State. Applicants must be physicians licensed in New York State, with experience of at least three years in active practice. Subjects of examination and relative weights: Questions relating to the duties of the position, 1; experience, 1.

Persons desiring to enter these examinations must file applications in the office of the State Civil Service Commission on or before October 20, 1915.

Obituary Notes.—Dr. FRANK D. VREELAND, formerly of Paterson, N. J., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1879, died at the home of his son in Passaic, N. J., on Oct. 4, aged 64 years.

Dr. WILLIAM H. KRICKBAUM, a member of the staff of the Pennsylvania State Hospital for the Insane, died of typhoid fever on September 21 at the age of 37 years. He was graduated from the medical department of the University of Pennsylvania, and he was a member of the Montour County Medical Society, and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. JOHN MERRICK BEMIS of Worcester, Mass., a graduate of the University of Vermont, College of Medicine, Burlington, in 1893, medical superintendent of the Herbert Hall Hospital, Worcester, and a member of the Massachusetts and Worcester District Medical Societies, died at the hospital on September 22, aged 55 years.

Dr. PRUDENCE FENNEMAN of Hamilton, O., a graduate of the Cleveland-Pulte Medical College, Cleveland, O., in 1899, died at the home of her sister in Canfield, O., on September 22.

Correspondence.

AN ANTISEPTIC PASTE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The wound application known under several names but chiefly as S. S. paste is brown sugar changed to the consistency of condensed milk by the addition of nitrate of silver and water (1 to 3,000) solution. It is applied to septic and sloughing or gangrenous wounds and the technique of its employment is to fill the wound with the 1 to 3,000 silver, then at once apply the paste and cover with the usual pad and bandage; but a fold or two of unbleached muslin has advantages over the ordinary gauze wipe for padding purposes, let the bandage itself be either gauze or muslin. The bandage may stick fast, but the cohesive is water solutive and consequently it is readily soaked off and re-

moved. Pastes have a place in wound treatments and the niche of this one is more or less wide, according to the judgment and the skill in manipulation of its employer. It is an honest paste and will perform just what its formula promises.

Manifestly the initials S. S. stand for Silver-Sugar, and the observation of two precautions is important. (1) The paste should be well rubbed up and free from lumps. (2) Any cakes, or remnants, remaining upon the skin beyond the reach of a more or less scanty discharge, and therefore undissolved, may be let alone, and a new application may be made without regard to them.

One position it does seem to hold without a rival and that is when an antiseptic must be applied through a window in a plaster of Paris cast. To use a colloquialism "it stays put."

DOUGLAS H. STEWART, M.D., F.A.C.S.
128 W. 86TH ST., NEW YORK.

INFESTATION WITH HYDATID.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD for July 31, I notice in the "State Board Examination Questions" the following: "What are the parasitic diseases that may be caused by eating insufficiently cooked meats?" This question is answered on page 213 as follows: "Infection by tapeworm, trichina, and by echinococcus."

I venture to call your attention to the fact that hydatid does not belong in the same category as tapeworm and trichina so far as mode of infestation is concerned. Larval tapeworms and larval trichinæ are muscle parasites which may develop to adult worms when ingested by suitable hosts in insufficiently cooked meats. On the other hand, hydatid in man arises, as you of course are aware, from the ingestion of the eggs of a dog tapeworm, a thing which conceivably could happen as a result of meat being contaminated with such eggs, but which probably happens, as a rule, from eggs on contaminated hands or vegetables. Hydatid infestation, therefore, belongs in the category of diseases due to lack of sanitary precautions and inadequate regard for cleanliness, just as do infestations with ascarids, whipworms, pinworms, etc., and not to the category of diseases due to eating improperly cooked meat, which diseases may arise in the midst of highly sanitary surroundings and the utmost cleanliness. As Dr. Stiles has put the case in his hookworm campaign, infestation with ascarids, whipworms, hydatid, and such parasites is indicative of coprophagy.

MAURICE C. HALL,
Assistant Zoologist.
BUREAU OF ANIMAL INDUSTRY,
WASHINGTON, D. C.

CLASSIFICATION OF MEDICAL LITERATURE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Permit me to correct a paragraph in the issue of your journal for June 5, 1915, which has come to my notice. In her article on "A Logical Classification of Medical Literature," Miss von der Osten metes out a certain degree of praise for a classification of anatomy published by me some years since. This work was given the series number 74, established for contributions approved by the Institut International de Bibliographie in Brussels. Miss von der Osten adds: "It may be obtained in this country through Dr. Herbert H. Field, of Brooklyn, N. Y." It is this statement that I wish to correct. The pamphlet is on sale by the Concilium Bibliographicum, Zurich, Switzerland (30 cts.). Its author, although a Brooklynite, left the City of Churches in 1885, so that the post would have some difficulty in finding him.

HERBERT HAVILAND FIELD, M.D.
ZÜRICH, SWITZERLAND.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCARCITY OF MEDICAL CANDIDATES FOR THE SERVICES—LEPROSY—ASSOCIATION FOR SCIENCE—SECTION OF PHYSIOLOGY—OBITUARY.

LONDON, September 25, 1915.

THERE is still a scarcity of candidates for medical officerships in the Army and Navy. It is announced that there will be vacancies for 2,500 within the next half year, though some practitioners have returned from the Colonies to take service. Sir Alfred Keogh is willing to extend the arrangements for granting commissions in the R. N. M. C. to residents of three months in general hospitals connected with schools who are registered, physically fit, and willing to be called upon if required on forty-eight hours' notice. Hospitals willing to assist can inform the war office the number of their beds and of their residents. It is thought that to some extent the hospitals will be secured against undue loss of their residents, who will be able to return, if need be, and will in any case have had some special training before they go. The scheme seems to promise a beneficial arrangement for all concerned.

The address on leprosy delivered at Dublin Academy last May by Dr. C. M. O'Brien has now appeared *in extenso* and deserves more attention than a report at the time could supply. It gives an excellent epitome of the history of the disease—once the most generally diffused and still perhaps the most fatal of all maladies. No modern writer has described it more accurately than the Greek authorities and Dr. O'Brien gives in detail the description of Aretæus, following it up with notes from Guy de Chauliac, John of Gladdesden, Glanville, and others, to illustrate its literature. In connection with this he considers the contagiousness and mode of infection. The question of bacteriology leads to the tuberculin and Wassermann tests, and so to the experimental transmission of the disease to animals and the artificial cultivation of the microorganism. The great difficulties encountered in its transmission to animals from injection or inoculation of nodules teeming with bacilli are freely admitted. Many series of negative results must be faced, but numerous as they have been they cannot destroy a single positive observation, and Dr. O'Brien related in full the history of a case in which his diagnosis was confirmed by Sir Thomas Myles and Mr. T. T. O'Farrell, the latter of whom prepared the slides and carried out the inoculations, the Wassermann test being applied by Prof. E. J. McWeeney. The conclusions submitted from this case were that it possessed many of the characteristics insisted on by ancient and modern writers, and showed that the Wassermann test was not specific for either syphilis or leprosy. Further, to him the tuberculin test carries little conviction. The portion taken from a nodule

of this patient and stained by the Ziehl-Neelsen method showed many bacilli, of which a few were seen within the cells, but the majority were scattered about the lymph spaces. Dr. O'Brien concluded by the reflection that the marked advance in the study of leprosy is overshadowed by the tragedy of events, as we have not a single cure to the credit of science, for "those cases cured by the Holy of Holies, as recorded in Scripture, come under quite a different category, of course."

The 85th annual meeting of the British Association for the Advancement of Science has been duly celebrated and as usual has presented both in the sections and in some of the papers composing them, many points of interest to the profession. The meeting was this year at Manchester, and there was a large attendance. Professor Bateson, retiring president, introduced his successor, Professor Arthur Schuster, who delivered his address, taking for his subject "The Common Aims of Science and Humanity." It was decided to hold next year's meeting at Newcastle-on-Tyne and Sir Arthur Evans was elected president. The social assemblies and entertainments which usually accompany this meeting were less numerous than usual on account of the war, but there was plenty to see in the city for those who were not familiar with it and hearty hospitality was shown by the citizens.

In the Section of Physiology Dr. C. E. Lea illustrated certain electrical methods of diagnosis in a case of auricular fibrillation which had been under observation for over two years, during which the pulse had been characteristically irregular but easily controlled by digitalis. Dr. E. P. Poulton brought forward points to show that the cause of diabetic coma is not a true acidosis. The blood, he remarked, is more acid in uremia and also during moderate exercise.

Prof. Herring read a paper on Thyroidectomy and Thyroid-feeding in reference to the effects on the adrenin content of the suprarenals. The experiments seemed to give uncertain results.

Dr. Graham Brown gave a lantern exhibition of the effects observed after the removal from a chimpanzee of the right, then the left, post-central gyrus, and lastly, the right motor area. Paralysis lasted for six days. Within 14 days action became apparently normal again and the animal could execute fine movements, even such as opening a door with a key. The operations had therefore not caused any loss of power for such fine movements.

Dr. D. Bridge Lees, consulting physician to St. Mary's hospital, died suddenly, as did his colleague, the senior surgeon, McOwen, of whose death I informed you a month ago. Thus St. Mary's loses two of her senior staff within a month. Dr. Lees was elected on the staff in 1880. He had been previously physician to the Hospital for Sick Children. He was Bradshaw lecturer to the Royal College of Physicians in 1912 and last July he was elected senior censor to that college. He contributed to the societies and journals, chiefly on thoracic and rheumatic diseases.

Lt. Col. J. J. Lampney, who retired in 1897, has died at the age of 65. He joined the service in 1877, was in the Ashanti Expedition, 1881; Senior Medical Officer of the West African Settlements, 1891-2, and on the Boundary Commission (Sierra Leone).

Dr. Archibald R. Douglas, medical superintendent of the Royal Albert Asylum, Lancaster, for 25 years, has died suddenly in the prime of life. He made interesting contributions to psychology.

Captain J. N. Armstrong, M.B., R.A.M.C., has been killed in action after serving several months in the Durham Light Infantry. He was senior moderator in natural science and gold medalist—aged 25.

Captain A. Hellas, I.P.H., R.A.M.C., killed in the Dardanelles, was senior medical assistant at Aberdeen Royal Asylum, but volunteered to the First Highland Field Ambulance on the outbreak of war.

Lt. V. T. Warren, R.A.M.C., was killed at the Dardanelles within a few weeks of arriving there with the Third Welsh Field Ambulance.

Lt. John Macadam, another victim of the war, died of wounds received at Gallipoli, aged 23. He joined the Territorial Force in 1912. He had been a student at St. Bartholomew's Hospital, but on the outbreak of war joined the active service.

Progress of Medical Science.

1. The Child and the Community. E. O. Otis.
2. Transvesical Prostatectomy. P. M. Pilcher.
3. A Study of the Effect of Rowing on the Heart. R. I. Lee, W. J. Dodd, and E. L. Young, Jr.
4. Experimental and Clinical Observations on the Blood Pressure in Spinal Anesthesia. G. G. Smith.

1. The Child and the Community.—E. O. Otis points out that the community is beginning to realize that diseased and physically unfit men and women should not be allowed to marry and produce diseased and physically unfit children. In two states, at least, so-called eugenic marriage laws have been enacted. Both for the child's sake and for the sake of the community who have to care for the defectives, such a law seems just and reasonable. It is a significant fact bearing upon this point, that the most important causes of infant mortality in New York City, as stated by Dr. Baker, chief of the Division of Child Hygiene of the Department of Health, in 1913, are the so-called congenital, inherited diseases, the deaths from which diseases occurring during the first month of life, amount to 35 per cent. of the total deaths under one year. To ensure a healthy child, pre- and post-natal care and training of the prospective mother is essential, and in many communities this is now done in connection with the lying-in hospitals, or, as in Boston, by the Child Hygiene Department of the Board of Health and other private instrumentalities through visiting nures who instruct the future mothers in personal hygiene, the general care of pregnancy, and in their own and their babies' care after confinement. The Caroline Rest Training School for Mothers, conducted by the New York Association for Improving the Condition of the Poor, is an excellent example of this kind of welfare work. After the child has graduated from its milk diet, the community has still a duty in seeing that it is provided with proper food. At school the child should be thoroughly examined from time to time for defects or diseases. Sixty-eight per cent. of the Boston school children have defects. The author tells of the Forsyth Dental Infirmary for Children which cost $800,000, and is endowed with $2,000,000 as an example of what should be done to protect the teeth of children. As most authorities now believe that the majority of cases of tuberculosis in adult life became infected in childhood, he points out the urgent need of combating this disease. He states that Hamburger has demonstrated that latent tuberculosis is present in 71 per cent. of children from seven

to ten years of age. This fact should make the community realize its duty in providing proper playgrounds, open-air schools and even preventoria or places in the country. The author concludes by making a plea that the community offer the child means of spiritual development as well as to provide for its physical well being and its mental training. He can see no other way for providing religious instruction in a communal way except through the medium of the public schools.

2. **Transvesical Prostatectomy.**—P. M. Pilcher states that the chief objection to the two-stage operation has been the discomfort due to leakage of urine over the abdomen of the patient. This has been overcome by adopting the following technique for the first operation: Preferably with the bladder filled with fluid, a suprapubic cystotomy is done under local anesthesia, using one-half to one-quarter per cent. novocaine solution to infiltrate the tissues. The points of the technique which he emphasizes are: 1. Exposure of anterior surface of bladder as high up as possible. 2. Making opening in bladder at least 3 inches from urethral opening. 3. Drainage of bladder by Pezzer catheter or Pilcher modification. 4. Purse-string suture around opening in bladder to secure water-tight joint, employing same principles as in drainage of gall bladder. 5. Immediate resuture of suprapubic wound, obliterating prevesical space, reconstruction of the facial planes, etc., and closing the wound without drainage except where button drainage tube emerges. The results of an operation by this technique are: 1. Primary union of wound in practically every case. 2. Absolutely dry wound without any leakage of urine. 3. Complete control of urine for tests. 4. Patient out of bed in twenty-four hours. 5. Half of the operation complete without anesthesia or surgical shock. As soon as the bladder can be safely emptied the suprapubic cystostomy should be done. In all cases of emergency, where there is active hemorrhage into the bladder, suprapubic cystotomy should be done. The author prefers to wait about ten days before removing the prostate.

3. **Effect of Rowing on the Heart.**—R. I. Lee, W. J. Dodd and E. L. Young find that an abundant and somewhat contradictory literature has grown up concerning the effect of exercise on the heart. They point out that James Mackenzie of England, with his wide experience in cardiac disease, seriously doubts the existence of the so-called "athletic heart"; and that Cabot in an analysis of 600 successive cases of failing heart was not able to attribute the cardiac impairment to athletics or exercise. For the purpose of making observations the authors selected three groups of students at Harvard—freshmen, candidates for the crew, and graduates who had averaged more than ten years of rowing. Their conclusions are: That there is very little difference in the size of the heart of men who have been rowing for two to four years and men who have been rowing over ten years. The hearts of these two groups are very slightly larger than the hearts of a younger group who have not as yet participated in serious competitive rowing. These differences seem to be explained by the differences in age and development. The only conclusion that can be drawn at this time from this particular study is that prolonged participation in rowing under the system now in vogue at Harvard University and the Union Boat Club of Boston does not materially increase the size of the heart when the heart is sound at the beginning.

4. **Blood Pressure in Spinal Anesthesia.**—G. G. Smith working with Dr. Porter in the laboratory of comparative physiology of the Harvard Medical School came to the following conclusions: The blood-pressure can be lowered as much by spinal anesthesia as by section of the cord in the cervical region. The greatest fall was caused by injection of the drug in the thoracic region, where the vasomotor fibers which supply the splanchnic area leave the cord. This part of the vasomotor mechanism is the first affected by the drug when the injection is made in the lumbar region. The extent of diffusion of the drug within the dural sac appears to be influenced more by the bulk of the solution injected than by any other one factor. A given amount of drug in a concentrated solution diffuses less and consequently lowers blood pressure less than does the same amount of drug in a more dilute solution. The greatest effects upon blood pressure were noted when adrenalin was combined with novocaine. Entire fixation of the drug does not take place within twenty minutes after the time of injection. When a solution of greater specific gravity than spinal fluid is used, the extent of diffusion may be increased by gravity. Attempts to raise the blood pressure by the intravenous injection of pituitrin or adrenalin gave only a very transient rise.

1. **A New Method for the Treatment of Inoperable Cancer.**—S. P. Beebe reports the results of treating cancer with extracts of a poultice powder originally applied by Dr. Horowitz which contains the following substances: Menyanthes trifoliata, melilotus officinalis, mentha crispa, brassica alba, anemone hepatica, viola tricolor, anthemis, fructus colocynthidis, lignum quassiæ, urtica dioica, radix rhei, hedge hyssop. These substances are in approximately equal proportions in the poultice, with the exception of the mustard, which forms twenty per cent. of the mixture, and the colocynth fruit, which is five per cent. A saline extract of this powder was used for hypodermic injection in the arm. A summary of 100 cases treated is given: Fifteen are clinically well; 7 are improved; and 28 received no benefit.

2. **The Autolysin Treatment of Cancer.**—H. S. Williams and J. W. Beveridge postulate that neoplastic cells are susceptible to the attacks of leucocytic enzymes, that there is a constant tendency to disintegration of some of these cells under the attacks of the white blood corpuscles. The white blood corpuscle is provided with digestive enzymes, and with a mechanism for the production of special proteolytes to cleave an endless variety of protein molecules; being unable, however, to complete the hydrolysis thus begun. The "autolysin" referred to by the authors and for whose action they seek an explanation is the extract of the poultice powder used by Beebe and described in the foregoing paper. This autolysin contains vegetable protein and is introduced into the circulatory system hypodermically where it constitutes an antigen stimulating chiefly the blood cells to give rise to defensive enzymes. These enzymes begin the disintegration of the cancer cells. In considering the possible influence of the chlorophyll in the autolysin or "poultice powder" from which the extract is made, the authors suggest that it may be a special stimulus to the white cells whose remote progenitors, living in stagnant water, came in

constant contact with vegetable cells containing it; and that the ancestral memory might very well leave the leucocyte still in condition to respond energetically to the primordial stimulus of chlorophyll. This food or stimulus directly supplied to leucocytes may be what enables them to make such rapid and effective attacks on the cancer cells when autolysin is administered.

3. **Infantile Eczema.**—H. W. Cheney emphasizes the following points: 1. Infantile eczema in the majority of cases is the evidence of a toxemia, intestinal in origin. 2. Such cases require primarily the services of a pediatrist to oversee the feeding, and only secondarily advice as to external medication.

5. **Backache.**—H. Weinstein discusses the diagnosis of the various pathological conditions which may give rise to backache. Lumbago may be an early symptom of tabes or osteomalacia. Myositis may be confounded with the rhachialgia of neurasthenia. Malignant tumors may give rise to pain as well as tuberculosis of the spine, arthritis, sacroiliac disease, or neuritis. Backache may be a premonitory symptom of smallpox; it may occur in Malta fever; or it may follow typhoid fever. Cancer of the rectum or obstruction of the sigmoid may cause pain in the back. Calculus in the pelvis of the kidney or in the ureter may cause pain in the back on the same side. Diabetes may be accompanied by backache.

2. **Relative Frequency of Ectopic Gestation.**—A. B. Spalding takes his clinic cases as a basis for his figures. Previously when his practice was limited to obstetrics he did not have a case of ectopic pregnancy in private or clinic work. It was only after he combined gynecology with obstetrics that he was called upon to treat cases. During the past three years he has operated on thirteen clinic cases. They were encountered at fairly regular intervals in a comparatively large number of patients in the out-patient clinics of the Leland Stanford University School of Medicine. During these years 36,668 patients in all were registered, and of this number, 2,995 were treated in the women's clinic. The thirteen cases were among these. The ratio for the whole outpatient clinic, corresponding to general practice, was 1 to 2,820 patients; for the women's clinic, corresponding to the specialist's practice, 1 to 227 women; for the obstetrical department alone, 1 to 131 pregnancies.

3. **Streptococcus Bacteriemia in Endocarditis.**—J. A. Oille, D. Graham and H. K. Detweiler working in the heart clinic recently established at the Toronto General Hospital had a case of a girl whose symptoms had been attributed to pulmonary tuberculosis, but who later had no cough and a too slow morning pulse rate. Yet she had slight fever twice a week. This suggested the taking of a blood-culture in accordance with Rosenow's method. Success along this line has been attained even beyond expectations, so that now cases formerly diagnosed as cases of chlorosis, anemia, indefinite fever, obscure tuberculosis, and nervous breakdown are being called endocarditis. The authors observed twenty-six cases and felt justified in coming to the following conclusion: 1. A streptococcus bacteriemia is present in the great majority of cases of active endocarditis and probably in all in some stage of the disease. 2. Endocarditis more commonly follows tonsillitis in children and young adult females than is generally believed. Possibly this accounts for the frequency of mitral stenosis in females. 3. This low grade streptococcic endocarditis is much more common than the so-called rheumatic endocarditis. 4. A large number of persons showing symptoms of the neurasthenic type are really suffering from a subacute streptococcic endocarditis. 5. Endocarditis may be active for considerable periods of time without symptoms. 6. A family incidence of tonsillitis and endocarditis (also appendicitis, gastric ulcer and other diseases which are often of streptococcic origin) is of frequent occurrence. 7. The pulmonary systolic murmurs so frequently found in "run-down" and anemic individuals are rarely functional.

4. **Prostatectomy Mistakes and Failures.**—G. S. Whiteside refers to a statement made by Young that when a prominent surgeon publishes a series of successful cases he incites many to try to imitate his success without proper instructions in his operation, or understanding of the procedure or of the dangers to which he subjects his patient. In addition to proper training in the technique of an operation, the author emphasizes the importance of a correct diagnosis before operating. Stricture of the urethra, spinal neuroses, cancer, and diseases of the kidneys or other organs are frequently overlooked. Careful diagnosis is necessary in determining in each case whether the perineal or the suprapubic route should give the better result. It is most important to determine the functional activity of the kidneys, in order to know the risk of uremia following the operation. If the kidneys are insufficient, spinal anesthesia is probably the safer method. It is of the greatest importance that the operator carefully supervise the after-care of the patient.

5. **Verumontanitis.**—W. J. Pennock calls attention to the inaccurate descriptions of the verumontanum as given by anatomists, for instance, Gray. Embryologically the veru is developed from the united lower ends of the atrophied Müllerian ducts. Rytina has demonstrated the veru to be made up of glandular tissue in its central portion, and urethroscopy has made evident the erroneousness of the previous descriptions by anatomists. Besides infection by pyogenic organisms, there are other etiological factors to which the author especially calls attention, as common causes of noninfective inflammation. They are: 1. Coitus interruptus. 2. Ungratified sexual desire. 3. Masturbation. The chief symptoms are urinary frequency, burning sensation in the deep urethra, diminution of sexual power, premature or delayed and painful ejaculation, and referred pain in the lumbar region, in the rectum, or in the testicle. The diagnosis is aided by an urethroscopic examination. Silver nitrate solutions are applied locally for the treatment of infected cases.

6. **The Combination Method in the Treatment of Cervical Carcinoma.**—S. M. D. Clark recommends that the internal iliacs and one ovarian artery be ligated as an adjunct to treatment of cancer of the cervix by the Percy heat method. He concludes: 1. The heat method alone has doubtful curative properties, and should be viewed in the light of a valuable adjunct in the treatment of cervical carcinoma. However, in extremely obese women, it offers the best and only chance for a permanent cure. 2. Heat should be used as a routine in all types of cervical carcinoma, except in

hopelessly advanced cases. 3. The ligation of both internal iliacs and one ovarian possesses definite merit, and when combined with heat, furnishes the best means of converting the borderline cases into frankly operable ones. 4. It cannot be too strongly emphasized that the combined application of heat and ligation of vessels, on the one hand, and total extirpation, on the other, in all except clearly operable cases, should be done as a two-stage operation. 5. In the combination of heat with starvation, we have a valuable means of markedly increasing the operability and of decreasing the primary mortality of radical extirpation. 6. Heat combined with extensive arterial ligation, followed by radical hysterectomy, offers the greatest possibilities for permanent cure.

1. **Bacteriology of Septic Wounds.** — A. Fleming, writing from the Research Laboratory attached to the General Hospital at Boulogne reports that the bacteriology of wounds inflicted in this war has furnished a very interesting study because the flora of these wounds has been found to be very different from that met in civil practice. Nearly all the wounds were due to bullets or fragments of shells and they seldom remained sterile. Pieces of mud-covered clothing were usually carried deep into the wound. To determine the relationship between the infections found in wounds and the bacteria on the clothing the author examined samples of clothing taken from wounded men on their arrival at the base. Small pieces were cut off from portions of clothing remote from the wound, so that contamination of the clothing by discharges from the wound might be avoided. Pieces about half an inch square were planted into broth tubes and cultivated aerobically and anaerobically. Of twelve samples of clothing examined, *B. aerogenes capsulatus* was found in 10, *B. tetani* in 4, streptococcus in 5, and staphylococcus in 2; while other organisms which were not properly identified, but which were in all probability mainly non-pathogenic, were found in some of the samples. These examinations were made in November last when there were many cases of tetanus, which is hardly surprising when it is considered that one sample in three of the clothes examined showed the presence of the tetanus bacillus. From a study of the bacterial flora it was noticed that these wounds pass through three phases, more or less distinct. The bacterial history of a wound is much the same whether it is slight or severe, except that in the slight and perfectly drained wounds the transition from one stage to another is much more rapid and healing occurs in a shorter time. Streptococci are found in practically all wounds, whether old or recently inflicted. The spore-bearing anaerobes, comprising chiefly *B. aerogenes capsulatus*, *B. tetani*, and some putrefactive organisms, on the other hand, progressively diminish in relative frequency as the age of the wound increases. In the early stages these spore-bearers are present in much greater numbers than anything else, whereas later, although they may still be seen in the pus films, their numbers are relatively few. The most striking feature of the discharges from these wounds was the extraordinary amount of pus—thus indicating that phagocytosis was very active and the resistance to the infection very great. This is in marked contrast to cases seen in civil practice where the infectious agent usually has enhanced virulence due to its passage from one individual to another, or where infections occur more or less spontaneously due to lowered resistance on the part of the individual. The author recommends the periodic administration of a vaccine to keep the patient's resistance up to a high level.

2. **Rhinophyma: Its Etiology, Pathology, and Treatment.**—W. Milligan is of the opinion that chronic alcoholism or traumatism are not etiological factors in producing rhinophymata. It may conceivably be an end result of acne rosacea which is very often present on the nose and in other parts of the face at the same time. Histological examination of sections of the pathological tissue removed by operation shows marked thickening of the connective tissue of the corium with hyperplasia and cystic dilatation of its sebaceous glands and small deposits of fat between the various hypertrophied areas. The outcome of these changes is an elevation of the papillary layer of the true skin into circumscribed projections of varying size and shape. Cystic dilatation of one or more of the sebaceous glands is, as a rule, a marked feature in many sections, and it would appear as if these glands were not only enormously increased in size, but were actually increased in number. Their ducts are in many cases greatly dilated and more tortuous than normal, while their epithelial lining is often considerably thickened. Blood-vessels, arteries, veins, and capillaries are enlarged, have thickened walls, and run a more tortuous course than is usual, while around them there are often cellular extravasations. The author reports a case successfully treated by dissecting away the hypertrophied tissue and putting two very thin skin grafts from the thigh in its place.

3. **Galyl, a Substitute for Salvarsan and Neosalvarsan.**—A. Foerster states that the drug referred to in this paper is a discovery of Dr. Mouneyrat, to whom we owe hectine, and is named Galyl (1116). Like salvarsan, it is a derivative of arsenobenzol, which was first prepared by Michaelis in 1881. In galyl two molecules of arsenobenzol are linked with two phosphoric groups; it is tetraoxy-diphospho-amino-diarsenobenzene, and it contains 35.3 per cent. of arsenic and 7.2 per cent. of phosphorus, is a yellow powder of a tint different from those of salvarsan and neosalvarsan, and is insoluble in distilled water. It, however, dissolves rapidly in a weak solution of sodium carbonate, from which it can be precipitated readily by the addition of an acid. The tubes in which the drug is dispensed, contain the small amount of sodium carbonate required for solution, and thus the handling and dissolving are no more complicated than in the case of neosalvarsan. The solutions are yellow, with a brownish-green tint when fairly concentrated, and differ considerably from the bright yellow of salvarsan solutions. Galyl is best administered by means of intravenous injections, as intramuscular injections are painful and may lead to necrosis like salvarsan. Any of the methods used for the latter drug are admissible. Salvarsan, whether employed intravenously or intramuscularly, does not yield any better results. Headache, slight fever, or diarrhea may be untoward effects. The dose of galyl for an adult is 0.3 gram. It is much less expensive than salvarsan.

1. The Treatment of Cholera by Hypertonic Saline Solutions During an Epidemic of Swatow, South China. G. D. Whyte.

2. The Administrative Control of Measles. R. M. F. Picken
3. Universal Suspension Apparatus for Arm and Leg. M. Sinclair.
4. An Operation for the Obliteration of the Cavity in the Tibia Remaining after Sequestrotomy. W. Gemmill.
5. The Treatment of Septic Wounds by the Electrolytic Bath. F. Fowler.
6. A Case of Hysterical Amblyopia. K. Campbell.

1. Treatment of Cholera by Hypertonic Saline Solutions.—G. D. Whyte says that the extraordinary effect of intravenous infusion in the collapse stage of cholera must be seen in order to be realized. Unfortunately this improvement is only transient unless the rapid passage of the saline solution from the circulatory system into the alimentary canal and its subsequent loss by vomiting and diarrhea is prevented. This is done by using a hypertonic saline solution—double the normal strength—as first suggested by Rogers. If the specific gravity of the blood of the patient is below 1.062 the injection of saline solution is not required. The blood pressure, degree of fever, and many other factors have to be carefully considered in determining the amount of saline to be injected and the frequency of the injections. The author gives tables and other data fully explaining the details.

3. Universal Suspension Apparatus for Arm and Leg.—M. Sinclair describes a form of suspension of the arm and a splint which allow all permissible movements of the limb and give great comfort to the patient, who is free to move at his will, or to sit up by his bedside if he wishes. For the leg he describes a suspension which consists of a fixed frame carrying a traveling cradle, from which the limb in its splint is suspended by a system of weights and pulleys as in the case of the arm. A patient with a fractured femur can raise his pelvis without other aid when supported in this apparatus. The author gives diagrams and full particulars.

5. Treatment of Septic Wounds by the Electrolytic Bath.—F. Fowler took up what seemed to be a fantastic idea. The answer to the question of how to attack germs in the tissues has been sought in the use of antiseptic lotions, vaccines, or serums. The discovery of Russ that nearly all germs are carried toward the positive pole of an electric current passing through a solution of sodium chloride, and that the small current required is fatal to the germs was seized upon by the author to answer the question, how can the germs in the tissues be induced to leave the deep parts, if we cannot kill them without also killing the tissues? The practical results of the treatment instituted by the author seem to support Russ' observations. The electrode connected with the positive pole of the battery is immersed in the bath with the wounded limb. The negative pole must be connected to some indifferent part of the body either through another bath or a moist pad. A current of 20 to 30 milliamperes, which the patient should barely feel, is sufficient for an ordinary bullet wound.

Artificial Cultivation of Variola-Vaccine Virus.—Proescher, who recently published an important discovery in regard to the bacteriology of typhus has now come to the fore with an article on the cultivation of the virus of smallpox-vaccine. After a review of the work in this field of his predecessors he expresses his belief that the virus is a filtrable microörganism, visible in dark field illumination, staining rather weakly. These bodies, by their action upon the tissues, cause the formation of certain reaction corpuscles which have sometimes been regarded as the cause of the disease. Von Prowazek's "initial corpuscles" may be a stage in the development of the true cause. Heretofore it has been quite impossible to demonstrate that this living virus is the actual cause of vaccinia. The author takes up the work at this juncture. Taking some U. S. Government vaccine he inoculated the cornea of a rabbit and produced a typical vaccine keratitis with an abundance of so-called Guarnieri's corpuscles. When the lymph was studied with the dark field minute cocci and diplococci were visible, as well as epithelial cells filled with the latter. Vital staining of these bodies proved impossible. The lymph was then diluted, rapidly centrifugalized, and the sediment placed on cover glasses in smears, the latter then dried and treated with various stains. The difficulty in staining may be due to preservation of the lymph in glycerin. After infinite pains in technique the author concluded that both intra- and extracellular forms of virus coexist, although the minute extracellular organisms must have originally escaped from the cells. The author succeeded in cultivating similar organisms from the unfiltered and filtered virus and from the cultures produced the characteristic keratitis in the rabbit but here the matter rests. We do not know what these bodies are—whether bacteria or protozoa—and as yet the subject of immunizing with cultures has not been studied, nor that of the formation of antitoxic or bactericidal antibodies. The first culture *in vitro* could not at first be propagated in media such as ascites and serum bouillon but after the addition of a carbohydrate like maltose a luxuriant growth was obtained under anerobic conditions. The author has now carried it through twenty-eight generations. The great difficulty lay in making the first culture. The virus seems to weaken rapidly in virulence in the incubator at 37° C. Strange to state when inoculated directly into animal tissues which have approximately the same temperature the virus maintains its virulence and multiples. As already stated glycerin is believed to explain this behavior *in vitro*. To obtain the first culture ascites fluid, guinea pig serum, and bits of aseptic kidney, etc., from the same animal are placed in a sterile tubule, and tested again for sterility after forty-eight hours in the incubator. One-tenth c.cm. sterile virus is then inoculated into the tube which is allowed to remain in the incubator for two weeks under strict anerobic conditions. The colonies are seen as a faint haze about the bits of flesh. Dark field illumination now shows that these are composed of the specific formations already described.

August 17, 1915.

Treatment of Chronic Cardiac and Renal Diseases with Acidylsalicoyl Derivatives of Theobromin.—Hoffmann refers to the original introduction into therapeutics of theobromin, which was followed by the mixture of theobromin-oodium and salicylate of soda, known for short as diuretin. Then came theophyllin, an isomer of theobromin, and called for short theocin. All these remedies are successful diuretics, and often one will succeed where another fails. The author, who began to try out these substances as far back as 1889, has tested recently the so-called acidylsalicoyl-theobromin, a true synthetic, which seems to embody all the advantages of its predecessors. He has treated 30 or more patients with nephritis, cardiac myodegeneration, mitral lesions and coronary sclerosis, the new synthetic unburdening the heart by its action on the kidneys even after digitalis preparations had shown their inadequacy to relieve the strain on the heart. The remedy in fact was tested especially in cases which did not respond to digitalis and the older diuretics. In but five cases did failure attend the use of the remedy, which as a rule

behaves as a synergist to the digitalis group. Nevertheless it is often able to do its work alone. It lowers a high blood pressure, which perhaps explains its power in true angina pectoris. Perhaps it should be regarded best as a potentized theobromin.

Nyctalopia at the Front.—Best states that justice has already been done by writers to day-blindness among soldiers, but that if we bear in mind that this war is largely one of might fighting, a corresponding literature on night-blindness has not been forthcoming. As a result of his own studies he has reached certain pertinent conclusions. Thus night blindness is favored by nocturnal activity, hardships, irregular meals, physical and psychical overexertion. In a small proportion of cases none of these factors was present. Essentially night blindness depends on some condition which compromises vision in general, such as anomalies of refraction or other objective condition first brought to light through trench warfare. The victims then find themselves unable to see what their comrades point out. The author finds no evidence of a special war nyctalopia. In 36 cases he found 4 of congenital or familial night blindness, while 21 had anomalies of refraction, chiefly myopia. In a small number of cases night blindness was connected with some local or general disease or with an affection of the eye itself; while in 2 cases there was apparently nothing to explain the condition. These soldiers really developed night blindness after trench life. A third victim without lesion was doubtless a hemeralope as well.

Ether-Saline Infusion in Tetanus.—Hercher describes a single case of recovered tetanus in which this remedy was tested, but the incubation period was 14 days, and the most that can be claimed is that the disease responded favorably to the treatment. The original wound, in the arm, was suspicious. The disease began insidiously as rheumatism, but the picture of tetanus was soon in evidence. Treatment was intensive—serum, magnesium, and morphine. The patient, however, seemed doomed so that a new resource was sought and found in the before-mentioned infusion. Fifteen cm. ether were added to 750 cm. of saline infusion, and the case at once took a turn for the better, the treatment being continued until recovery.

Anatomical Changes in Hereditary Diseases, Especially Diabetes.—Ribbert mentions some familial diseases which are quite without anatomical changes—color blindness, hemophilia, certain psychoses, polyuria. In other cases anatomical alterations represent the totality of the affection—polydactyly for example. These types have nothing in common with acquired anomalies of the germ cell or with malformations due to amniotic adhesions. There are nevertheless doubtful cases which fall under none of these heads. We cannot say offhand in the absence of anatomical alterations that the cells of an embryo are constitutionally inferior because of arrested development. If, however, secondary degenerative processes set in we may postulate the existence of such inferiority, yet there is always a possibility of an exogenous disease factor. In regard to ordinary diabetes we can blame pancreatic organic disease, perhaps, but in congenital diabetes we do not find this mechanism. If there is any pancreatic alteration it is perhaps restricted to too few Langerhans islets. The author recalls a case of diabetes (not known to be familial) in a young man whose islets were so few that only one was found in 25 large sections. Heiberg and Weichselbaum have obtained the same find in diabetes in children. The condition could of course be congenital without being familial. Another explanation naturally obtrudes itself, to the effect that the number of islets was originally normal, but had been reduced by inactivity-atrophy because of functional incompetency. Another assumption is that some unknown irritant or injury has functionally weakened islets, which were unusually vulnerable. We can of course speak colloquially of "weakened" islets, as distinct from organic lesions of the pancreas, and of quite different import from greatly reduced number of possibly normal islets. "Weakness" may be made synonymous with vulnerability. These refinements, however, cannot aid in explaining familial diabetes which is known to follow Mendel's law. The author states that all future studies must distinguish between acquired and inherited diabetes.

Fatal Case of Pyorrhea Alveolaris.—Clemm relates the case of a man of 37, civilian, admitted with a so-called gum boil and buccal suppuration. The abscess was incised and H_2O_2 used freely as lotion and dressing. The temperature ran up in a couple of days to 105° F. No other suppurative focus could be located. There was a most foul odor from the mouth. All of the symptoms however, appeared to abate spontaneously. The cheek, which had swollen greatly, began to return to its normal size, the fever subsided to a remittent type, and the bad breath improved. Three loose back teeth which had literally swum in pus were now extracted from the right lower jaw. At intervals all the remaining teeth in this jaw were also removed, along with bone sequestra. The fever did not subside and eventually became high. The patient was now in a state of marasmus. The lower jaw continued to slough, pus formation increased, and death supervened under the picture of sepsis, with terminal pulmonary lesions. Death was explained by necrosis of the jaw, burrowing of pus and septicopyemia. The intensive implication of the jaw followed an ordinary case of Rigg's disease.

Effect of Athletic Training on Blood Pressure.—W. S. Middleton notes a proportionate decrease in both systolic and diastolic blood-pressure during the training period. With a period of rest succeeding the training period there occurs a rise of systolic and diastolic blood-pressure beyond the anteseason records. The blood-pressure reaction to the given test of fifty stationary running steps is scarcely altered by a period of training. As a basis for explanation for these phenomena several hypotheses are stated: The decrease of blood-pressure during training may result from an enlargement of the vessels to the skeletal muscles with a lessened peripheral resistance. Or this lessened peripheral resistance may result from a compensatory vasodilatation to accommodate for the increase in cardiac output and work from athletic training. From the vascular standpoint the secondary rise of blood-pressure after a period of rest would be explained by the logical assumption of a return of normal vasomotor tone, which in the presence of an hypertrophied myocardium, or an increased cardiac power, would lead to an increased blood-pressure from a relative increased peripheral resistance with an accompanying increase in systolic output. Moderate peripheral sclerosis from overstrain would likewise give increased resistance with a tendency to higher blood-pressure than normally existed in a given individual. The primary decrease in blood-pressure after a period of training may be the result of a temporary moderate cardiac dilatation. By a return of the normal myocardial tone with rest and the development of cardiac hypertrophy the increase of blood-pressure during this period may be explained.—*American Journal of the Medical Sciences.*

Insurance Medicine.

Goiter and Life Expectancy.—C. H. Mayo and H. S. Plummer say that the apparent prevalence and increase in goiter has aroused much interest in the subject during the past few years. Recording the dangers of surgical mortality will be of general benefit, since in the report of operative deaths lies the best incentive to avoid the dangers, low though they may be, of late operation by early treatment.

The defect of being born without a thyroid results in the unintelligent human dwarf who seldom reaches the age of puberty. These children are known as cretins and may be somewhat benefited by thyroid feeding. Most animals are fortunate in being endowed with a superabundance of each of the various ducts and ductless glands, which permits a wide variation in their functional activity and also permits the removal of large quantities of the gland without apparent loss to the system. It is estimated that the growing child needs one-third of the total thyroid generally found in normal individuals, while the adult seemingly may maintain perfect health with one-sixth of the gland. A minute amount of the secretion seems to act as a hormone which maintains the necessary stimulation of the other kinetic glands of the body with associated function. Some operators maintain that the total removal of the thyroid in the adult is harmless and is indicated in diseased conditions. We should caution against the total removal of the thyroid except in malignancy.

The four parathyroids so intimately connected with the thyroid in location and function should be preserved with equal care from injury at operation. Undoubtedly two, and possibly one of these glands, may be sufficient to maintain function; but the danger of creating a deficiency of thyroid and parathyroid secretion is doubled when the operation on the thyroid is extended to removal or partial removal of both lobes, unless care is exerted to keep in front of the posterior capsule. If accidentally removed the parathyroids should be reinserted in an adjacent location in the field of operation. Thyroid and parathyroid feeding should be combined with the administration of lactate of calcium to control muscular spasm. With actual loss of glands the outlook is serious. If due to loss of circulation later improvement is to be expected. While deaths from tetany represent but a fraction of 1 per cent., even this slight mortality is unfortunate because it is usually preventable.

Investigations of Rosenow and others who have made cultures of the crushed tissue of diseased thyroids show that bacteria can be cultivated from some of the glands. While very suggestive, the exact relationship of these bacteria to the disease has not yet been sufficiently investigated to make any assertions. Acute infections are very rare as is also tuberculosis. A late manifestation of lues is probably a factor in more cases than is generally supposed. The mortality from infections other than surgical is so slight as to hardly need consideration.

Malignant degenerations are very rare. Carcinoma is more frequent than sarcoma, while both together represent less than 1 per cent. of the operations upon more than 1,300 new cases of goiter seen at the Mayo Clinic in 1914.

Simple goiter or a simple increase in the size of the gland may occur at any period of life but is quite common at puberty, an edematous swollen gland containing watery colloid and gland secretion. Such glands are subject to fibrous, cystic, or calcareous degeneration. There is, however, a change that occurs after many years in such glands which produces a train of symptoms not unlike the worst symptoms of exophthalmic goiter. Such cases are more fatal than the average exophthalmic goiter. The mortality in these cases from operation is not less than 5 per cent.

Plummer calls attention to a point in support of this theory, to which little attention has hitherto been paid, that an individual aged 22 years, with an adenoid of the thyroid, has a definite chance of developing a train of symptoms during the thirty-sixth year so similar to the symptom-complex associated with hyperplastic thyroid that the best trained diagnosticians are constantly confusing the two conditions. Of 916 operations performed in the Mayo Clinic for simple goiters during the year 1914, 801 of the cases were female and 115 male. With regard to exophthalmic goiter some cases run an acute course to death in the first months, a slightly larger number in the latter half of the first year, at which time the most marked effect is shown on the heart, liver, kidneys, and nervous system. It is during this period that the operative mortality is highest. After the first year these cases fluctuate with severe exacerbations, down to a base line which is far above normal. A few patients apparently make a fair recovery with or without medical treatment; but relapse is common. As for the age incidence of exophthalmic goiter of the 386 cases seen in the Mayo Clinic during the year 1914 the greatest number of cases occurred between the ages of 20 and 30 and 30 and 40. Of these 386 cases 323 were females and 63 males. From a surgical standpoint operations often aided by medical treatment cure exophthalmic goiter in 70 per cent. of cases. About 16 per cent. of the remaining cases are notably improved. About 4 or 5 per cent. have been operated on when the degeneration of the essential organs had become permanent and there was little hope of improvement, but the progress of the disease has been checked. In younger individuals about 5 per cent. with the same type of degeneration slowly make a partial recovery on account of their youth. The immediate mortality in exophthalmic goiter is about 3 per cent. The mortality in simple goiter without complications is largely due to surgical accidents and need scarcely be considered. The mortality in degenerating simple goiter, the socalled thyrotoxic goiter, is high; we should place it at least 2 per cent. greater than exophthalmic goiter.

Relapses occur in about 10 per cent. of cases of exophthalmic goiter. The mortality from secondary operations is exceedingly low.

There is a relapse of an appreciable degree in about 10 per cent. of the cases of degenerating simple goiter. About 5 per cent. of patients have secondary operations.—Medical Section of the American Life Convention.

Insurance for Wife, Effect of Divorce.—The benefit accruing from a policy of life insurance upon the life of a married man, payable upon his death to his wife, naming her, is held in Filley *v.* Illinois L. Ins. Co., L.R.A. 1915D, 130, to be payable to the surviving beneficiary named, although she may have years thereafter secured a divorce from her husband, and he was thereafter again married to one who sustained the relation of wife to him at the time of his death.

Book Reviews.

SENESCENCE AND REJUVENESCENCE. By CHARLES MANNING CHILD of the Department of Zoology, the University of Chicago. Price $4.00. Chicago: The University of Chicago Press, 1915.

ALL who are interested in the deeper problems of biology, and especially zoologists who have followed the work of Prof. Charles Manning Child as it has appeared during the past ten years in various journals, will welcome the summary of his results just published by the University of Chicago Press under the title "Senescence and Rejuvenescence." Under this modest title are concealed the foundations of a distinct theory of biology.

The material for Professor Child's investigations has consisted chiefly of fresh water Planarians, a group of flat worms that under experimental conditions show extraordinary plasticity of structure. A piece of a worm may be reconstituted into a whole worm like the original, except in size. But no part can reconstitute parts anterior to its own level unless the head region is formed first. Each part dominates the parts posterior to it. The degree of dominance is associated with the rate of metabolism. The latter, as measured by the production of carbon-dioxide, is found to be parallel to susceptibility to poison, which is the test usually employed by the author.

New individuals, whether produced artificially or by normal reproduction, either sexual or by fission, show a higher rate of metabolism than do older individuals. Differentiation and growth are associated with an increase in the physiologically stable constituents of the cells of the body and a decrease in the rate of metabolism. This is the basis of senescence, and if continued leads to death. Rejuvenescence is a reduction of the stable constituents and an increase in the rate of metabolism. This takes place in starved planarians, in pieces separated from the body by cutting or by normal fission, and in eggs during the early stages of development; but not in germ-cells before fertilization. The mature egg or spermatozoon is an old cell, highly differentiated (in this the author differs from Minot). The sexual reproduction fertilization is the stimulus that starts the process of rejuvenescence.

The life-cycle consists of growth and differentiation alternating with reduction and dedifferentiation. But the rate of metabolism is not the same in all parts of the body. It varies progressively along certain axial gradients. The chief one of these is in the longitudinal axis of the body, and the highest rate is in the head. During normal development differentiation begins in the head; and, in general, a part having a higher rate of metabolism dominates and controls the process in adjoining parts having a lower rate.

These observations and inferences are among the more striking ones that form the basis for a theory of the organism that is neither vitalistic nor chemical, and is diametrically opposed to the "corpuscular" theory of Weismann. It is a physicochemical theory, in which the living organism is defined as "a specific complex of dynamic changes occurring in a specific colloid substratum which is itself a product of such changes and which influences their course and character and is altered by them." The organism is compared to a river. "From the moment the current begins to flow it is a constructing agent, *i.e.* it determines form along its channel, and from the same moment the structure already existing affects the flow of the current." While rejecting entirely the idea of a preformed and continuous germ-plasm, the author recognizes that orderly development and definite form are characteristics of organisms. These are accounted for by some form of stimulus arising in the dominant center of the organism.

While these views are interesting, stimulating, and in harmony with certain present-day ideas in biology, to the reviewer it seems rash to reject results obtained from the study of higher organisms, in which nature has analyzed the functions of the body. This seems especially true of the mass of evidence collected by a host of investigators, which goes to show that there is a germ-plasm resident in the nucleus of the cell, that it is multiplied at each cell-division, and that it is of so definite a value that the presence or absence of a group of definite characteristics of the body may be traced to the presence or absence of an individual chromosome in the germ-cell. We await with interest the fuller discussion of reproduction that Professor Child promises for another time.

A TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN GLAISTER, M.D., D.P.H. (Camb.), F.R.S.E.; Professor of Forensic Medicine and Public Health in the University of Glasgow; Ex-President and Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow; Licentiate of the Royal College of Physicians and Surgeons of Edinburgh; Examiner in Medical Jurisprudence and Hygiene to the Royal College of Physicians and Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow for Diplomas in Medicine and Surgery, and Examiner in Public Health for the Diploma in Public Health of these United Corporations; formerly Examiner in the University of Birmingham; Senior Medico-Legal Examiner in Crown Cases for Glasgow and Lanarkshire, etc. Third edition. With 137 Illustrations and One Colored Plate. Price $5.00 net. New York: William Wood & Co., 1915.

THIS is a volume of 857 pages of which the first 597 are devoted to the subject of medical jurisprudence, and the remainder to the subject of toxicology. Medical jurisprudence is dealt with in a manner strictly in keeping with the thoroughness with which this field has been covered in England. Stress is laid chiefly upon English principles and procedure, which while they may not answer all the needs of the American student, nevertheless give him a broad foundation in the general theory of medical jurisprudence. However, only a relatively small portion of the book deals with the English procedure. The main body of the work presents a detailed exposition of medical jurisprudence in its universal aspects and in its latest developments, including such subjects as personal identity, anthropometry, finger prints, identity of the dead, death in its medicolegal relations, wounds, blood-stains and their examination, impotence and nullity of marriage, etc. The concrete case reports contribute materially to the interest and lucidity of the text. These case reports constitute also an important feature of the section on toxicology. The book contains a large number of illustrations.

OVERCROWDING AND DEFECTIVE HOUSING IN THE RURAL DISTRICTS. By Dr. HARVEY B. BASHORE, Inspector for Pennsylvania Department of Health. Author of "The Sanitation of a Country House," "The Sanitation of Recreation Camps and Parks," "Outlines of Practical Sanitation." First Edition. First Thousand. Price, $1.00 net. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Limited, 1915.

THE title of this book of 92 pages fully indicates its content and scope. The observations were made in a typical American rural farming community in which conditions almost as bad as those in city slums were found. The subject matter is discussed under the following chapter headings: Land Overcrowding, House Overcrowding, Defective Building, Overcrowded and Defective Schools, and Results. The effects of rural overcrowding and defective housing are summed up in lack of efficiency, disease, and premature death to many. A series of fifteen full-page reproductions of photographs accompany the text. The book is an original and valuable contribution to American public-health literature.

TASCHENBUCH DES FELDARZTES. II. Theil Herausgegeben von Generalarzt. Professor Dr. AD. DIEUDONNÉ, Geheimrath Professor Dr. M. V. GRUBER, Professor Dr. H. GUDDEN, Oberstabsarzt z. D. Dr. W. HASSLAUER, Privat-Dozent Dr. W. HEUCK, Stabsarzt Professor Dr. FR. SALZER, Oberstabsarzt Professor Dr. G. SITTMANN, Professor Dr. W. SPIELMEYER, Professor Dr. W. WEICHARDT. Zweite, neubearbeitete Auflage. Price, 4 Marks. Munich: J. F. Lehmann's Verlag, 1915.

A special wrapper informs us that this edition has incorporated the experiences of the present war. The book is of pocket size, and bound in flexible covers. Two features, always noticeable in works of this class, are in full evidence here. First, the clean cut, axiomatic statements concerning diagnosis and treatment, which as a rule serve to give character to such publications. Second, the wholly unsatisfactory attempts to supply effective data when such do not exist. This is seen in the specialties. If an ordinary army surgeon, perhaps with no special training could recognize and manage cases of—for example—dementia precox, according to the principles laid down here, there would be no need for psychiatrists.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-eighth Annual Meeting, Held at Pittsburgh, September 14, 15, and 16, 1915.

THE PRESIDENT, DR. CHARLES L. BONIFIELD OF CINCINNATI, IN THE CHAIR.

Further Experiences with Local Anesthesia in Herniotomy.—Dr. J. H. JACOBSON of Toledo, Ohio, said that at the Providence meeting of the Association in 1913, he reported twenty-eight operations for the radical cure of inguinal hernia performed under local anesthesia. Since that time he had made ninety-six operations by the same method. The following was a tabulation of all operations: 96 operations for radical cure of inguinal hernia; 6 operations for radical cure of strangulated inguinal hernia; 7 operations for radical cure of femoral hernia; 5 operations for radical cure of strangulated femoral hernia; 3 operations for incarcerated femoral hernia; 2 operations for incarcerated umbilical hernia, and 5 operations for incisional hernia, a total of 124. There had been no deaths. His further experience with this method of performing herniotomy had convinced him that whenever possible, such operations should be performed under local anesthesia. The only exception to this rule should be in herniotomy in children and where the operation must be performed in uncontrollable nervous adults. The latter exception in actual practice was not so frequent as one would think, for the reason that most nervous individuals could be controlled by carefully explaining to them the nature of the operation and the reasons for operating under local anesthesia. A preliminary hypodermic injection of morphine and scopolamine was usually sufficient to allay all nervousness and the operation could proceed even in nervous patients with the same facility as under general narcosis. In only three of the operations was it necessary to complete the operation with a slight amount of ether. These were among the earlier operations. Local anesthesia recommended itself for hernia operations because it insured the patient absolute safety. No other form of anesthesia gave the same degree of safety as did the modern Braun technique of local anesthesia. When a surgeon had mastered the few principles which were necessary for success in local anesthesia he would soon abandon all other anesthetics in herniotomy. He had never observed the slightest toxic effect from the use of the ½ per cent. novocain and adrenalin solutions which he had employed for these operations. The frequency of hernia in otherwise normal individuals should make it the most common of all surgical operations. This would be the case only when the entire surgical profession would give such patients a method which involved no danger to life and which gave a maximum of cures. These conditions were at the present time best fulfilled by the use of local anesthesia in such hernia operations.

Dr. JOHN W. KEEFE of Providence, R. I., said his experience was in accord with that of the essayist. He had done a number of hernia operations with the aid of local anesthesia. Recently he had been using morphine and scopolamine previous to using cocaine and adrenalin. He found the scopolamine occasionally made the patient so excitable that in a few instances he had had to defer the operation to another day. This might be due to some peculiarity on part of the patient. Most of the operations for inguinal hernia could and should be done under local anesthesia.

Dr. ALBERT VANDERVEER of Albany, N. Y., said he had gradually reached a point, he thought, when the majority of the profession were in favor of local anesthesia, and yet the subject was not definitely settled because it should receive a good deal of consideration not only from our State but our national associations. He did not believe a hernia operation should be undertaken in children under local anesthesia. He believed a general anesthetic was best for that purpose.

Dr. WILLIAM H. HUMISTON of Cleveland, O., stated that any one who had seen Dr. Jacobson operate under local anesthesia would be convinced that he was a master of that art. In following an exclusive method of anesthesia, one was inclined to make every patient submit to that form of anesthesia, and in his early work he soon found out that this was poor judgment. It was necessary to select our cases.

Dr. JACOBSON, in closing, said he did not think we ought to consider local anesthesia without adopting the modern technique of Braun, and we ought to eliminate cocaine on account of the disturbances following it and the danger attending it. When one became familiar with local anesthesia and the method of giving it, it would appeal to him. His plea was to get more of these cases of hernia on which to operate as we could assure these patients absolute safety.

A Case of Intestinal Obstruction and Volvulus.—Dr. RUFUS B. HALL of Cincinnati, reported a case of intestinal obstruction and volvulus, caused by a large gallstone. He emphasized the statement that the profession generally did not regard gallstones in which the patient was not a great sufferer, as surgical. These cases were treated by physicians most contentedly and hopefully, with very indefinite results so far as any permanent relief was concerned, being variously described by such vague terms as stomach symptoms, discomfort after meals, indigestion, neuralgia, gastritis, liver derangement, etc., and treated for years without any permanent benefit. He believed that they were surgical and he would recommend exploratory operation in all those chronic cases in which there was a clear past history of one or more acute attacks. If an exploration was made at that time, it would not be a serious operation and would avoid many of the serious complications that were likely to develop later. In those cases in which the stone, through ulceration, passed into the bowel, the patient was subjected to great danger, even if he did not survive. That any of them survived the many dangers attending this tedious process was marvelous. When intestinal obstruction occurred, it was so many years after the acute attack that the real cause was not recognized until revealed at the operation or autopsy. The long past history of gallstone was ignored or forgotten. He thought the advanced treatment of exploratory incision which he recommended for this very large class of suffering patients ought to be recommended by all men engaged in special abdominal surgery, and thereby educate the family physician to call consultation in these cases more frequently than was the custom at the present time.

Dr. HUGO O. PANTZER of Indianapolis stated that the case cited by the essayist brought to his mind one instance which was to him very instructive. The first case was reported by Dr. Elsner, Rochester, N. Y., about twenty odd years ago. In that case a stone of similar size to the one described by Dr. Hall following a history of gall-bladder trouble was attended by attacks of acute obstruction. The case, when seen, in each of the attacks, showed a different part of the abdomen to be the seat of obstruction, and when finally the stone was passed by the rectum the thing was easily explained. The stone created local irritation, and within the musculature the adjacent parts would open spastically, close upon it, and the obstruction was explained in that way. Under the influence of medication, and in one or two attacks without medication, immediately preceding the spasm relaxed and the stone went farther down. This was unusually interesting inasmuch as it was complicated with volvulus, and he believed Dr. Hall's case was about the only one of the kind ever reported.

Dr. FRANK D. GRAY of Jersey City said that all of us every now and then learned from our own experience and observation of others the importance of dealing with abdominal conditions promptly. If this particular case had been operated upon promptly there was no doubt that woman's life could have been saved, and the plea he would make was to give heed to the undoubted and persistent symptoms, go in, find the trouble, and relieve it.

Dr. FRANCIS REDER of St. Louis said this case was of interest from two points of view. First, what a gallstone could do; second, the promptness with which the patient died after the operation without regaining consciousness. An interesting feature was the cause of death which the essayist attributed to the violent peristalsis. There were other factors to be considered. The principal one was that of anesthesia which might be looked upon as a contributory cause of death in this case. He presumed it was a general anesthetic. The resisting power of the patient had been underestimated. He should say that the case was one for local anesthesia and for exploratory operation.

Dr. GORDON K. DICKINSON of Jersey City stated if 30 per cent. was our accurate diagnostic value in the abdomen, then operation should be done promptly, and more on suspicion than on an accurate diagnosis, more

on opinion that something was wrong than to wait until we felt that something was positively and surgically bad. In Europe, in Mexico, and in the abdomen, watchful waiting was bad policy. In going over his cases and studying them carefully he found that death in many of them was due to dilatation of the right side of the heart which came on quickly after an abdominal operation, partly due to the anesthetic, and partly due to the condition of the heart before he took the case. The fact that the abdomen was relieved of its pathology made him feel that possibly in the case of Dr. Hall there was a right-sided heart failure.

Dr. J. Henry Carstens of Detroit agreed with the essayist and with Dr. Gray that we did not perform these operations early enough. If we could make a diagnosis and resort to an exploratory operation promptly, we would never have so many of these cases go to the bad.

Dr. Magnus A. Tate of Cincinnati said the case reported by Dr. Hall reminded him of one he saw five years ago. A woman, sixty years of age, had been complaining of progressive pain and tenderness for a number of years. One day she was taken with severe vomiting, which kept up, the abdomen was distended, and he tried his best to persuade her that a section was necessary. She refused to undergo an operation. Later she was operated on, and a large stone, 2½ inches in size, was found in the intestine, about 6 inches from the gall-bladder. The intestine was gangrenous and ready to burst. In making the resection a portion of the contents escaped into the abdominal cavity. The patient went into a state of collapse and died about three hours after the operation.

Dr. John F. Erdmann of New York City said he had had five cases of intestinal obstruction from gallstone in the past ten years, and of this number four died. Strange to say, the recovery was in a woman, seventy-two years of age, upon whom he did an enterosotomy and appendectomy. She also had a large tumor of the right ovary which was mistaken for appendicitis.

Dr. Herman E. Hayd of Buffalo said he recalled a patient, a woman, seventy-nine years of age, who had practically no symptoms. So far as the passage of a stone was concerned, she never had an attack of violent pain, and yet the stone found was as large as a small hen's egg. He was called to see her when she was having fecal vomiting. She vomited for two days. Finally, he operated, removed the stone, and she lived five days after the operation. There was no history of ulceration nor of an inflammatory attack. The stone was found in the bowel and the symptoms were those of intestinal obstruction.

Dr. Albert Vander Veer of Albany, N. Y., stated that in his collection he had a specimen which he obtained many years ago. A patient whom he had attended some fifteen years previously, was taken very ill and had what he supposed was an acute jaundice. He recovered from this attack and lived fifteen years afterward in good health. At the time of death, he was allowed to make an autopsy. He suspected he had some malignant disease of the intestinal tract. He found a direct communication between the neck of the gall-bladder and the beginning of the transverse colon. He believed this man in his previous illness had passed through a form of sickness that had resulted in relieving the gall-bladder of gallstones, and they had passed out through the large intestine. The fistulous tract gave him no great inconvenience.

Dr. Charles L. Ill of Newark, N. J., stated of forty cases operated on by his brother and himself they found three large gallstones in the small intestine. In one case they found a mass between the small intestine and the gall-bladder. Three large gallstones were passed through ulceration into the intestine, caused obstruction, and killed the patients.

Dr. D. Tod Gilliam of Columbus, Ohio, said that when we spoke of being unable to find a gallstone or gallstones near the lower part of the ileum, there was reason for it. The upper part of the intestinal canal was larger in caliber than the lower, and a gallstone would pass down pretty well toward the entrance of the ileocecal region before it became inspissated, and the lower part of the ileum was less distensible than the upper part. This should teach us the lesson that whenever we found great distention of the abdomen along with obstruction, it should always remind us there might be gallstones at the bottom as a factor.

Dr. John Norval Bell of Detroit, asked the question, how do these large stones get into the bowel? The case he had would perhaps elucidate that in a measure. A woman, sixty-seven years of age, who had never had any pain, but simply heaviness and fulness, had a palpable tumor of good size. It was hard to determine its nature. On opening the abdomen he found it was a large thickened gall-bladder full of stones. There was one stone four times the size of the one Dr. Hall had described.

Dr. William Edward Darnall of Atlantic City said he recalled a case he saw a year or two ago on which he operated on the diagnosis of appendicitis with all of its symptoms, and when he got inside he found a small puddle of pus and fished out a stone about the size of a goose egg. It was about ⅛ inch thick, with a hard shell of calcium salts. This enterolith, which it was undoubtedly, had got several accumulations of bile salts which under some circumstances went on to a full gallstone. The question we wanted to think about was, what was the composition of the stone?

Cholecystectomy versus Cholecystostomy.—Dr. L. W. Swope of Pittsburgh said no absolute rule could be laid down to guide one in determining when cholecystectomy was preferable to cholecystostomy, yet there should be some way of ascertaining why there was so much higher percentage of cures after removal of the gall-bladder than after draining. From the former cases in the patients who survived operation and answered my inquiries he got a report of 96.8 per cent. cures, and the remainder suffered from symptoms probably indicating associated gastric or pancreatic disease. On the other hand, in cholecystostomy there were only 74.8 per cent. of cures, the remainder being no better and many of them worse than before operation. In considering the latter it was of course true that in many of them the disease was so advanced and adhesions so extensive that removal of the gall-bladder was out of the question because of its high mortality in such cases. There were still a large number where it seemed to be reasonable to suppose that better permanent results would have been obtained by removal of the gall-bladder instead of drainage. This argument received verification in the results obtained in the two-stage operation where for some reason he decided to drain the gall-bladder at the first operation and remove it four to eight weeks later. The question was how to decide intelligently between these operations. It was again a matter of mortality which was slightly higher in cholecystectomy than in cholecystostomy, 2.3 per cent. as compared with 2.5 per cent. The former was cut down by choosing the drainage operation whereas the conditions indicated increased risk from removal of the gall-bladder. The dangers of cholecystectomy included possibility of injuring the ducts, vessels and surrounding viscera from the manipulations necessary to free the adhesions. When adhesions were so extensive that the removal of the gall-bladder would be attended with marked traumatism and left large areas of raw surfaces to be covered, then because the primary mortality was so high and the hope that subsequent complications would not arise, was so uncertain, that he believed better results were obtained by drainage of the gall-bladder. While he believed that a diseased gall-bladder, like a diseased appendix, should always be removed when possible, still there were exceptions. Because primary removal of the gall-bladder opened up so many tracts for the possible extension of infection, and because exprience had shown that occasionally a patient did die from acute sepsis in infections of this kind, he was convinced that such a gall-bladder should be drained with as little manipulation as possible. Then at the end of four to eight weeks, if recovery was comparatively complete, the gall-bladder should be removed, as these were the patients who were left with a chronic infection which advanced so insidiously that years might elapse before return of symptoms; but when they did return the involvement of the upper abdomen was frequently too extensive to permit complete removal and ultimate cure. These cases also offered favorable sites for subsequent malignant degeneration. In advocating cholecystostomy in infective cases he did not include hydrops and chronic empyema of the gall-bladder in a quiescent state as cholecystectomy was safer where the infection had ceased to be active.

Dr. John F. Erdmann of New York City stated that last year he presented to the Association 300 and some odd cases of gall-bladder operations, with a mortality rate that to him was rather shocking because he did not feel that he had secured such a low mortality as he should have done. He was speaking more of the mortality rate in association with that presented by the

author of the paper. As to cholecystectomy versus cholecystostomy, he said that activity, efficiency and morbidity were the things all of us should consider to reduce the mortality to the lowest point. Anything that would increase efficiency must of necessity decrease morbidity, and cholecystectomy without any question limited morbidity and increased efficiency. As a result of his statistics last year he had been doing cholecystectomy practically in every case. There were some cases, however, in which on must do cholecystostomy.

Dr. C. S. FOSTER of Pittsburgh said that was an indication for taking out gall-bladders that were without symptoms. For instance, if one suspected the ducts to be enlarged and the glands enlarged down along the ducts, independently of pancreatic disease or of involvement of the viscera of the stomach, he knew that such a gall-bladder was infected and ought to be taken out.

Dr. JOHN W. KEEFE of Providence, R. I., said that we ought not to operate during the acute stage of inflammation in gall-bladder disease. Occasionally, we would have a perforation and have gangrene, and there would be a few cases in which it was necessary to operate during that period, but if one could keep away from operation and wait until convalescence was established, he would meet with greater success when he did operate.

Dr. FRANCIS REDER of St. Louis said that in regard to feeding a patient who was deprived of bile salts, on ox-gall, if one was reasonably certain that the patient's bile was in a normal condition one could feed that patient with his own bile by simply making him drink it. He would reject it, but by introducing the bile through a stomach tube the patient would retain it.

Unusual Contents of Inguinal Hernia.—Dr. CHARLES W. MOOTS of Toledo, O., reviewed the literature of hernia and reported the following case: Mrs. S., aged 38, resident of Detroit, family history unimportant. She had never suffered any illness necessitating her remaining in bed. She never had any suggestive urinary symptoms, furthermore, her first menses occurred at 12 years of age, were always painful, periods too frequent with profuse flow, the hemorrhages being increased the past year. About nine years previously she noticed a lump the size of a hickory nut in the region of the right internal abdominal ring. It remained about the same for eight years, when it came lower and appeared to double in size. At this time it also became very painful. Operation was performed August 22, 1914, under preliminary hypodermics of morphine and scopolamine, nitrous oxid and oxygen, and field-blocking anesthesia. He made the usual skin incision and then found that the mass could not be pushed upward into the inguinal canal as it was adherent to the labium majus. An elliptical portion of the labium majus was excised in order to free the mass which now gave him the impression that he was dealing with a kidney. However, it being almost beyond the point of identification, an opening was made in the peritoneum, when the right kidney space was explored and found deserted. It then occurred to him that it was well to know something at least of the left kidney. Sweeping the hand across the peritoneal cavity, the left kidney was found normal as to size, location, and feel. Dropping the hand into the pelvis he found what proved to be a parovarian cyst, 3½ inches in diameter, a subperitoneal fibroma the size of a walnut located on the fundus uteri, and a hydrosalpinx of the right tube. The exploratory incision into the peritoneum was then quickly closed, followed by a nephrectomy of the useless right kidney, and the inguinal canal closed in the usual manner. Time from starting the gas was forty-two minutes. A medium incision was then made, the parovarian cyst, the uterine fibroid, and right tube were removed, followed by the usual closure. The time of this latter operation was twenty minutes, making in all one hour and two minutes for the period of anesthesia. The kidney was composed of a mass of small cysts about ½ inch in diameter. The recovery of the patient was uneventful, and she left the hospital at the end of two weeks in fine physical and psychical condition.

The Surgery of the Appendix.—Dr. JOHN W. KEEFE of Providence, R. I., stated that in a series of 129 cases occuring in his service at the Rhode Island Hospital it was found necessary to drain in 65 cases, showing the tendency of the profession to delay operating. During four months he operated 52 times with one death; 50 per cent. of the cases were drained. The morbidity in these drainage cases should be avoided. The tendency to a long drawn out convalescence, to fecal fistula and secondary abscesses, was unfortunate to say the least. He operated on most of the cases shortly after they left the hospital. The Ochsner treatment was not understood by the profession and consequently had done great harm. Rapidity in operating was essential when the patient was prostrated. The surgeon should not attempt too much; open the peritoneal cavity, attend to the pathology found as quickly as possible, drain and close the wound, as far as the drain, with quickness. Stab-wound drainage was usually not necessary, but occasionally might be of service. The after-treatment consisted of the Fowler position, withholding the food, lavage of the stomach, if necessary, frequent rinsing of the mouth, tap water by rectum and small doses of morphia. On the third day the bowels were moved by enemata, and he had found eserine and pituitrin in some cases of value where distention of the abdomen with gas was troublesome. Appendicitis was a disease amenable to surgery. Early operation by a competent surgeon should be attended with no mortality. When he knew this to be a fact and realized how easy it was to remove an appendix in the first twenty-four hours of the disease, was it not regrettable to hear of so many patients dying from this affection? Both the physician and the laity were to blame. They must become enlightened and though much had been said and written on the subject it was our duty to continue to raise our voices and to cry out, "Don't kill with cathartics." Make the diagnosis early. Advocate operation before the end of the first day and see to it that a man well qualified to do surgery performed the operation.

A Prognostic Sign in Acute Suppurative Peritonitis.—Dr. HUGO O. PANTZER of Indianapolis, Ind., said that the presence within the abdomen in cases of peritonitis of a free or encapsulated serous or seropurulent fluid, which was practically without odor, by the side of encapsulated foul material, indicated a strong systemic defensive activity of distinct prognostic value. There were cases of peritonitis which by their violent symptoms and the conditions found at operation, included no apparent hope of recovery, and which notwithstanding made straightway for recovery. It was of prognostic interest to know the signs which at operation in a given case revealed this probability. In June, 1906, on a very hot summer day, which seemed to accentuate the gravity of the case there was brought to him a male baby of six months, which a few days before had become acutely ill and had at once and thereafter revealed the characteristic signs and symptoms of an acute general peritonitis of probable appendiceal origin. The temperature was 104°, pulse feeble and 170 to the minute. At operation there was found much free fluid within the abdomen, cloudy with pus, but odorless; and about the ileocecal coil were extensive adhesions enclosing an abscess containing about 45 c.c. of creamy and extremely foul pus and the gangrenous appendix. The case seemed utterly hopeless, yet it turned straightway to recovery. With three drainage tubes within the abdomen the very next day the child was found cooing merrily and taking its mother's milk, and from that time on it began to recover speedily. With many subsequent cases revealing a similar experience, it might now be set forth that such finding had a reliable prognostic value. The defensive material thus produced by Nature in single instances might vary in its characteristics. Notably it might be merely clear serum or quite cloudy, and it might be free within the abdominal cavity or encysted in one or more pockets. Conversely, the original morbid material might be variously encapsulated in one or more pockets, and even vary in degree or even kind of odor as pertaining to the several pockets in a given case.

Abnormality of the Sigmoid.—Dr. BUDD VAN SWERINGEN of Fort Wayne, Ind., reported a rare congenital abnormality of the sigmoid in a woman, 37 years of age, who had suffered from childhood with constination. Palpation of the abdomen elicited tenderness and tumefaction in both flanks. By the vagina the mass in the left side was felt to be very hard and larger than that on the right. A diagnosis of malignancy had been made by several consultants on this finding. The abdomen was opened by a median incision. The omentum was firmly adherent on the left side, but was finally loosened and packed back out of the way. The tuboovarian abscess on the right side was removed. The appendix, which was adherent to it, was also removed. In enucleating the left tube and ovary, which were very intimately adherent to the sigmoid, there was uncovered a cylindrical structure about 6 inches long, apparently coming out of the side of the sigmoid and entering the lateral aspect of the rectum. After freeing it, it was thought to be a diverticulum open at one or

both ends. As the main channel of the bowel was thought to be still uncovered the diverticulum was ligated at the sigmoid and rectal attachments and removed. The left ovary and tube were now enucleated and removed. Preliminary to closure of the abdomn water was run into the rectum, it being his custom to allow two quarts to run into the bowel. It was then found that the sigmoid and descending colon could not be filled and that he had evidently destroyed the only passageway between the rectum and colon. He therefore, anastomosed the rectum and sigmoid by the Noble method at the site of the former channel. The woman made a satisfactory but prolonged convalescence, and went home with a fecal fistula for which she was successfully operated May 11, 1915. His reasons for thinking it was a congenital defect and not a part of the sigmoid compressed by the exudate of a salpingitis and pelvic peritonitis were four, namely: 1. The history of lifelong constipation and necessity for taking cathartics. 2. The tube did not come off of the sigmoid at its end nor did it enter the top of the rectum. 3. The ballooning of both the sigmoid and the rectum showed a process which must have antedated the pelvic inflammation. 4. The walls of this tube did not correspond to those of a compressed tube, that is, they were not thrown into folds and by no kind of incision on or around the tube could its calibre be increased to that of normal bowel.

Some Observations upon Postoperative Ureteral Fistulæ.—Dr. HENRY DAWSON FURNISS of New York City said the proper care of ureteral fistulæ depended upon a knowledge of the natural history, a careful study of all the conditions, and selecting the treatment that was going to give results. He thought that he had been to conservative in attempting to save kidneys that were functionally of no value, and that in this so-called conservatism he had risked too much. It was useless and unwise to attempt a ureteral and vesical anastomosis in the cases where there was serious renal damage. The operation was attended with more risks than a nephrectomy and should success follow, the drainage into the bladder from an infected kidney was in itself harmful.

Mesenteric Thrombosis; Report of Two Cases.—Dr. WILLIAM EDGAR DARNALL of Atlantic City believed that infection played a decidedly more important part in the etiology of mesenteric thromboses than we had thought in the past. Recent studies went to show what a tremendous element infection was in all the ordinary types of embolism and thrombosis, such as occurred in the saphenous and pelvic veins, the lateral sinus, the uterine sinuses and other parts of the anatomy. It was only reasonable to infer, therefore, that the cases of acute mesenteric thrombosis were the result largely of some focus of infection, such as appendicitis, gall-bladder infection, ulceration of the intestine or even of metastasis from a distant focus of infection. The superior mesenteric artery was most often the seat of the trouble. Any other treatment than operative need not be considered. It was generally agreed that resection of the involved gut should be done, but many cases had been lost which possibly might have recovered if the anastomosis had been delayed and a secondary operation done later. The reason for this was that one could not be certain that the gangrene had reached its limit and would not extend farther and that the complete operation was apt to involve more time and trauma than the patient could stand. These patients were usually in bad condition when they came for operation. It was therefore better, according to Jackson, that the gangrenous portion of the gut should be brought well out of the incision, leaving full liberal margins at both ends. The gut should be resected and the ends of the same sewed into the wound which was walled off with gauze. With both ends of the intestine thus opened distention might be relieved and signs of further extension of the gangrenous process watched. At a later day, if the patient survived, the fistula might be closed and an anastomosis done.

Remove the Uterus Instead of the Ovaries for Incurable Cases of Menstrual Disorders.—Dr. J. HENRY CARSTENS of Detroit stated that all cases that required the establishment of the menopause should be subject to hysterectomy, leaving the ovaries. Vaginal hysterectomy was preferable, but if there were extensive adhesions and other obstructions that required celiotomy, then suprapubic hysterectomy could be performed, leaving one or two ovaries.

The Use of Sodium Citrate for Direct Blood Transfusion.—Dr. CHARLES B. SCHILDECKER of Pittsburgh said the use of sodium citrate for direct blood transfusion in human beings had been suggested by Hustin of France in 1914. In the Argentine Republic a number of investigators had had success with this substance. Lately in New York, Dr. Richard Lewisohn and Dr. Richard Weil had reported success by the use of sodium citrate in blood transfusion. At first he was afraid that the toxic effects of sodium citrate were such that it would not be advisable to use it. He was studying the effect of citrate blood transfusion and would report on that subsequently. In order to make transfusion a simple procedure so that it could be easily performed, an apparatus was devised for this purpose. It consisted of a glass stopper, graduated cylindrical container, so made as to have a side tube near the top. The bottom of the vessel was drawn to a tube about a quarter of an inch in diameter bent at right angles. Accompanying the apparatus were two glass cannulæ, one male and one female which fitted in and on respectively the end of the container. The method of performing the transfusion was as follows: Under all aseptic and antiseptic precautions, the male tube was inserted into the vein of the donor and the female tube into the vein of the recipient. The tubes were so made that they could be securely fastened in the veins. Bull dog clamps could occlude the veins at any moment. The apparatus was then connected with the cannulæ in the arm of the donor. Five c.c. of a 10 per cent. citrate solution were put into the vessel and the blood allowed to run, gently stirring with a glass rod to effect a good mixture of the blood and the citrate solution. The blood was allowed to run until the required quantity had been obtained. The clamp was then adjusted so that the blood flow ceased. The thumb was placed on the side tube and the apparatus removed from the female tube and adjusted on the arm of the recipient. The blood was allowed to run in. The whole procedure should not take more than ten minutes. The advantages of this apparatus were: (1) The whole procedure was visible. (2) No hurry was necessary. (3) The exact quantity of blood taken could be measured. (4) It did not require much experience to use it. (5) It could be used in a private office or dwelling; it needed no hospital surroundings. (6) The operation was not an unsightly procedure.

President's Address; Some Comments on Present-Day Tendencies in Gynecological and Obstetrical Practice.—Dr. CHARLES L. BONIFIELD of Cincinnati stated that one method of diagnosis strongly recommended by some operators in recent years seemed to him to be seldom needed. He referred to the opening of the uterus. The greater one's familiarity with intraabdominal conditions the less frequently he found it necessary to do an exploratory abdominal section. Hysterotomy would find more frequent employment in the hands of the general surgeon who had broadened his field to include gynecology than in the hands of a gynecologist who had studied at the feet of a master of the art. It was from the laboratory rather than from the operating room that further success in dealing with cancer was to be expected. The importance of early diagnosis and operation was thoroughly recognized by the surgeon, if not by the laity, and the radical and painstaking operations now performed had merely reached the limit as to thoroughness. Further experience with radium had pretty well demonstrated the position it should occupy in cancer therapy. In estimating the results of a given treatment of cancer it was to be remembered that cancer differed materially in the degree of its malignancy. Dr. Harvey Gaylord had called attention to the fact that some of the tumors with which he succeeded in inoculating mice had such a low degree of malignancy that even incomplete removal served to cure the animal. The surgical treatment of uterine fibroids in the hands of an operator skilled in pelvic surgery was now so successful and satisfactory, that any other form of treatment would have to show brilliant results to supplant it. Much interest had been shown in the toxemia due to colonic stasis. He had read two short papers on this subject before the Association, and he saw no reason for changing the opinions expressed in them which might be summarized as follows: (1) Preventive treatment was of prime importance; (2) medical and hygienic treatment brought relief in a large proportion of cases: (3) in a smaller number of cases some form of surgical treatment offered the only hope of relief; (4) ileosigmoidostomy gave the best results; (5) it was not usually necessary to remove that portion of the bowel whose function was eliminated by this operation. As to the administration of anesthetics, he preferred his anesthetics to be given by

some one whose knowledge of anatomy, physiology and therapeutics enabled him to meet emergencies that might arise without much direction or supervision on his part. The professional anesthetist was a useful member of the profession, but naturally liked to magnify his calling, so he provided himself with expensive and complicated apparatus that made the operating room look like the inside of a submarine. He did not claim that nitrous oxide was not a useful agent, and that there were cases where it was preferable to either ether or chloroform, but he did claim that it had not been proved that gas was safer than ether as the routine anesthetic for major surgical operations. Pituitrin had been introduced and twilight sleep was abroad in the land. It was claimed by some good observers that the physiological action of pituitrin was identical with that of ergot and that twilight sleep had benefited some sensational magazines more than it had parturient women. But the family physician of to-day was little better prepared to meet and grapple with the real problems of obstetrics than was his predecessor of a quarter of a century ago, and it was by the family physician that the majority of cases were attended. One of the main reasons for unsatisfactory progress was that obstetrics was inadequately taught at the medical colleges.

Newer Conceptions of Intestinal Stasis.—Dr. GEORGE W. CRILE of Cleveland said experimental research had shown that indol and skatol, the typical products of intestinal stasis, produced widespread changes in the brain, the adrenals and the liver; that one of the immediate effects on the adrenals was an increased output of adrenin; and that the iodin content of the thyroid was modified. In other words, indol and skatol produced effects similar to those produced by chronic infections, excessive emotion, or excessive exertion. The histological changes produced by all these conditions were identical. He, therefore, contended that intestinal stasis was an etiological factor in those diseases of which chronic infections, excessive emotion, and excessive exertion were etiological factors. In operative cases of intestinal stasis the procedure of choice was the resection of the cecum and ascending colon, making a lateral anastomosis between the ileum and the transverse colon near the hepatic flexure and buttressing the closed end of the ileum and the transverse colon against each other to prevent later dilatation.

Gas Pains.—Dr. GORDON K. DICKINSON of Jersey City referred to the varied terminology due to the etiology, and spoke of the improvement in technic changing the extent of the reaction. He referred to the physiology, normal and pathological, of the intestinal tract, and the causes of the gas syndrome, and made some comments on the relation of the same to shock. He also alluded to preventive measures and spoke of the treatment, such as position of the patient, enemas, proctoclysis, the use of Kemps' tube, etc.

A Contribution to the Conservative Surgery of Chronic Intestinal Stasis.—Dr. HAROLD D. MEEKER of New York City said that chronic intestinal stasis was a recognized factor in producing many pathological conditions. The existence of bands, folds or veils, which might interfere with intestinal function, challenged dispute. The problem confronting the practical surgeon to-day was not how these bands were formed, but rather how best to remedy the condition as it existed and to prevent re-formation. The surgical relief first offered was so radical, that many conservative members of the profession were frightened from further consideration of the subject. A few surgeons adhered to the Lane technic, but many had striven to modify it. These modifications served chiefly to prove the tolerance of the intestinal tract to abuse. Very little had been written on the therapeutic possibilities of conservative plastic surgery as bearing on this subject. Surgical interference was indicated only when mechanical interference to drainage existed.

(To be continued.)

"Smokers' Patches" in the Mouth. — Landouzy describes these as consisting of whitish lines or triangular patches extending from the juncture of the lips to the first molar. These are also known as smoker's commissural patches. They are found exclusively in syphilitics. Tobacco is merely the local irritant which causes the patches to develop in the predisposed.—*Presse Médicale.*

NEW YORK ACADEMY OF MEDICINE

SECTION ON PEDIATRICS.

Stated Meeting, Held April 8, 1915.

DR. WALTER LESTER CARR IN THE CHAIR.

Anti-Mumps Inoculation.—Dr. ALFRED F. HESS presented this communication, in which he stated that it was well known that an attack of mumps conferred immunity on the subject. This had been the general experience and it had been his in the Hebrew Infant Asylum. During the winter of 1912-13 there was an epidemic of mumps in the institution which included one hundred cases. This winter there had been a similar epidemic of eighty cases. None of the children who had the disease in the 1912-13 epidemic had the disease during the past winter. It was evident that since the organism causing mumps had not been isolated they could have no vaccine or serum, but in view of the fact that immunity was acquired by having the disease, it seemed that they might hope to confer immunity by the use of the blood of patients covnalescing from the mumps. The Hebrew Infant Asylum furnished a favorable opportunity for trying this experiment since they had the advantage of knowing the past history of the children with a considerable degree of accuracy, and knew just what diseases they had had. Twenty children who had not had mumps before were inoculated with the blood of convalescent children, using six to eight centimeters of the blood from the vein of the elbow of the donor and injecting it intramuscularly. These twenty children were divided into three groups; those of the first were inoculated with the blood of patients who had just recovered and in whom there was still some swelling of the parotid; a second group were inoculated with blood from patients about ten days recovered from the disease, while in the third group blood from children who had had the disease several years ago was used. The injections were made when the epidemic had reached considerable proportions. All the children were then exposed to the mumps in the mumps wards. In all of the wards in which the children were exposed mumps occurred to a considerable extent after these children were exposed, but not one of the inoculated children contracted the disease. In one ward eleven susceptible children contracted the disease, while not one inoculated child did so. The same fact was shown throughout the series. The results seemed to be the same whether the children were inoculated with the blood of those recently convalescent from the disease or those who had had it several years before. Dr. Hess said he felt that the epidemic had been limited as a result of this method of inoculation and was convinced that this method was a simple preventive of mumps in an institution. Of course, in choosing the convalescent donors they should be careful to exclude syphilis. The method was applicable in a family in which one child had the disease and it was desirable to protect others. As the incubation period of mumps was long, about eighteen days, the injection could be given to other children in the family with every prospect of averting the disease. The length of time during which the immunity lasted had not yet been determined, but it very likely lasted throughout the period of exposure. On the whole, it seemed better to take the blood of recent convalescents rather than that of children who had had the disease several years before.

Dr. SAMUEL FELDSTEIN of Brooklyn asked Dr. Hess whether he had any records of the inoculated cases as having been in beds adjoining the cases that contracted mumps.

Dr. GEORGE DOW SCOTT asked Dr. Hess if the blood of the patients having had mumps some months or years previous was less efficacious than the blood of patients who had recently had the disease.

Dr. WALTER LESTER CARR asked whether the children who were inoculated developed any constitutional disturbance or whether any local reaction was observed.

Dr. HESS, replying to these questions, said that there had been no local and no constitutional reaction. As to whether the blood from the more recent cases was more efficient than that from older cases it was difficult to say, but he felt inclinded to believe that blood taken from a case at about the end of the disease gave the highest immunity. As to the exposure of the inoculated children, they were kept in wards with children who had the mumps, and who were kept in bad while they had fever and after the fever subsided were up about

the wards mingling with the other children. He did not see how a more thorough exposure could have been made. Dr. Hess thought this method might be made use of in other infectious diseases in which immunity was conferred by one attack. Possibly it could be applied in measles, but not in so great a degree, and perhaps at some future time they might learn to apply it in scarlet fever.

Clinical Distinctions between Cerebral Intoxication, Meningism (Serous Meningitis), and Meningitis.—Dr. HENRY HEIMAN emphasized the importance of recognizing, if possible, the distinctions between these conditions. He said that cerebral intoxication was fairly frequent in severe infections. In the matter of cerebral complications pneumonia stood at the head of the list, while typhoid fever, influenza, scarlet fever, acid intoxication, and other diseases and conditions had a similar tendency to develop secondary meningeal symptoms. In practically all of these cases autopsy revealed no lesions of the cerebrospinal system. In distinguishing clinically between cerebral intoxication and meningitis it must be borne in mind that: (1) There was always an etiological factor to which the meningeal symptoms were secondary; (2) that the signs in cerebral intoxication were significant of a general cerebral irritation, while in primary meningitis there were in addition distinct focal signs; (3) that lumbar puncture was the most important and definite means of differentiating the two conditions. In intoxication the spinal fluid was sterile and clear; in meningitis bacteria would in most cases be found in the fluid, either by smear or culture, and the appearance of the fluid would be changed from the normal. The cytological examination of the fluid was also significant; in the intoxication cases no variation from the normal occurred, whereas in meningitis various changes were present, depending upon the type of infection, that was, whether it was meningococcal, pneumococcal, influenzal, tuberculous, etc. When the ordinary clinical and laboratory methods were not sufficient to distinguish between the two conditions, lumbar puncture was not only justifiable but necessary, even in the presence of acute infection, like pneumonia or typhoid fever. Meningism was a term first proposed by Dupré at the Medical Congress at Lyons, in 1894, to include all those cases clinically resembling meningitis, but in which lumbar puncture revealed a sterile fluid. The causes might be classified as infectious or toxic, irritative, reflex, or hysterical. Dr. Heiman said that in his opinion, the term meningism meant a greater degree of cerebral toxemia than was found in the condition called cerebral intoxication, and differed from it only in showing evidences of increased intracranial pressure and by a symptom complex which still more resembled true meningitis. Auto-intoxication and acidosis were among the most important diseases producing meningism, which was fairly frequently mistaken for meningitis in children. Here the differential diagnosis must be made by frequent observation and by lumbar puncture if necessary. Meningism might occur in the later stages of gastroenteritis, where the symptoms might be so marked as to point to a diagnosis of tuberculous meningitis. Of the irritative causes of meningism might be mentioned head injuries, some subacute and chronic ear conditions, and operations on the cranium or upon the venous sinuses. Under the reflex causes of meningism helminthiasis might be included as a possible factor. Hysterical meningitis had been mentioned rather extensively by the French, but Aporti believed that these cases were not hysterical or psychogenic in nature but rather toxic or infectious in origin. The points of difference between meningism and meningitis were: (a) the presence of one of the above-mentioned etiological factors in meningism; (b) the transitory character of the symptoms in meningism (that was their subsidence when the etiological condition improved); (c) the ophthalmoscopic findings (in meningism one rarely found ocular changes); (d) the bacteriological and cytological findings in the cerebrospinal fluid in meningitis. This latter must be regarded as the most important differential sign. Among other conditions which might simulate meningitis were pachymeningitis hemorrhagica interna, which was characterized by enlargement of the head, its distinguishing features being punctate or striated hemorrhages in the retina, and hemorrhagic fluid on puncture of the anterior fontanelle, while the spinal fluid remained clear. The etiology of this condition was supposed to be a preexisting hemorrhagic rhinitis of diphtheritic or streptococcic origin. Another condition that might be mistaken for meningitis was pachymeninigitis interna luetica. Encephalitis in early infancy could only be distinguished from meningitis by lumbar puncture.

Dr. L. E. LEFRETA said that certain it was that without lumbar puncture a diagnosis could not be made in very many instances. It was, perhaps, advisable to resort to lumbar puncture earlier and more frequently than had been brought out in the paper. The significance or the presence or absence of cerebral tâche and of Kernig's and Babinsky's signs in making a differential diagnosis between true meningitis and conditions simulating it might have been emphasized. If there was any doubt one should resort to lumbar puncture to see what the spinal fluid showed. In view of the fatality of true meningitis it was advisable to make a lumbar puncture early, for if one found a turbid fluid there was a good chance that it might be due to the meningococcus or to the influenza bacillus, for both of which the serum treatment was available. Where the infection was due to the pneumococcus or to the streptococcus secondary to a streptococcus infection in some other part of the body the prognosis was hopeless. In cases of severe malnutrition, meningismus might be met with and here the marked retraction of the neck, the great irritability, and the hydrocephalus made the case appear to be one of meningitis. In these cases of malnutrition, the fontanelle was deeply sunken, and while this was rarely true in tuberculous meningitis it was of good prognostic significance. As the child improved the fontanelle filled and the retracted neck soon came to its normal position. A distinction must also be made between poliomyelitis with symptoms simulating meningitis and true meningitis, and here the spinal fluid cell count and the globulin content and the way they changed offered a means of making a differential diagnosis.

Dr. FENTON B. TURCK said he thought sufficient emphasis had not been placed on the fact that in young animals and in children the bacteria passed readily into the walls of the intestinal tract; they passed through the submucosa, between and never through the cells, and were destroyed there or in the blood. While they did not form toxins within the lumen of the intestines when passing through the mucosa into the wall, they produced a distinct anaphylaxis. Dr. Turck said he had recently seen several cases that presented the symptoms of meningitis, but on microscopical examination and cultures, organisms were found of the *B. coli* groups, sometimes in symbiosis with cocci in the blood and urine. In these cases it was the native bacteria that were at fault. Three or four cases within six weeks mistakenly diagnosed as meningitis was quite a large number, and the examinatien showed at once that the invasion was from the intestinal lumen. The use of vaccines in these cases offered great advantages, together with the administration of the deficient internal secretions, elimination of the infection from the intestines, and the use of alkalies to overcome acidosis. This system of treatment, together with the withdrawal of food, or giving only arrowroot, had been very effective.

Dr. MORRIS STARK said that it seemed to him that with these three conditions it was simply a question of degree. Dupré, who first discussed meningism, discussed it from the standpoint that in this condition there were no lesions, but that the symptoms were the result of irritation of the meninges, and he came to the conclusion that there was some actual change in the spinal fluid, a chemical change, or a change in the leucocytes. In the very fulminating cases the reason one found no germs might be that the patient died before pus formation had had time to take place. One should also take into consideration the difference in reaction to irritation. Different groups of children reacted differently; the spasmophiliacs were sensitive to a marked degree to meningeal irritation and then there were children who did not respond so easily. In the cases due to intoxication from the intestinal tract, the results were probably produced by bacteria in the spinal fluid, but the changes were so unimportant that they were undetected. Retraction of the neck was a very common symptom in all manner of sickness in babies, and in making a diagnosis of meningitis it became a question of the degree of retraction and the amount of force necessary to overcome it.

Dr. ROYAL STORRS HAYNES said that in reference to serous meningitis complicating indigestion he would like to call attention to the fact that there was a type of cases in which the fontanelle was not retracted, as Dr. Le Fetra had correctly indicated to be the rule, but, on the contrary, the exudate caused a distinct distention and the fontanelle was hard and without pulsation. He had seen such a case with Dr. Le Fetra in

which the child had been ill with gastrointestinal intoxication and showed the symptoms of meningitis. The fontanelle was full, hard, and showed no pulsation. While considering the advisability of lumbar puncture the child began to improve and pulsation returned to the fontanelle. It was interesting to correlate this case with a full fontanelle and symptoms of meningitis with those cases in which the fontanelle was sunken.

The Surgical Treatment of Disease of the Stomach in Children.—Dr. ANGELO L. SORESI presented this communication. He stated that the main reason why surgery on the stomach resulted in so many failures in children was that the attending physician referred the patient to the surgeon when already in a hopeless condition. Surgery should always be a late resort, but the attending physician should keep in mind the possible necessity for surgical intervention and refer the patient to the surgeon in time. In injuries of the stomach intervention should be immediate when the child was brought to the surgeon immediately after the wound was inflicted; if he was brought later the expectant treatment was better, because many wounds of the stomach in children healed spontaneously. Expectant treatment was imperative if the child was first seen many hours after the accident. In experimental work wounds of the stomach in which the stomach was cut clean through with the scissors for about the length of a centimeter, the mortality of absolute noninterference was about 30 per cent.; the mortality of intervention after twenty-four hours was 80 per cent.; the mortality after three hours was zero. Foreign bodies did not often cause serious trouble in the stomach for the reason that when they passed into the stomach they generally passed into the intestine and were expelled. However, they might locate themselves in the lower part of the esophagus and require removal through the stomach. Medical treatment was absolutely powerless if the foreign body caused serious trouble, such as hemorrhage, perforation, or occlusion. Stenosis of the esophagus near the cardia was caused by the passage of caustics or might be congenital. If the passage of sounds through the mouth could not be effected, the indications for surgical intervention were not doubtful. Stenosis of the pylorus was a condition peculiar to young children and was more common than was generally supposed. Generally it came on suddenly in well-nourished children born of healthy parents. At times the symptoms in the beginning were slight, but in others the symptoms were very definite and one could note the peristaltic movement of the abdomen. The loss of weight was very remarkable and rapid at the beginning, then became slow and progressive. The appearance of a tumor on the pylorus was not an absolutely reliable sign of stenosis. Stenosis of the pylorus could only be mistaken for spasm of the pylorus or some kind of intestinal obstruction. By referring to the anatomy of the stomach one could not fail in making a diagnosis. If no bismuth passed through the pylorus after three hours one could feel sure that he was dealing with a true stenosis of the pylorus. The question whether one was dealing with a real spasm of the pylorus or with a growth of the pylorus was exceedingly difficult to answer. The spasm might cause a hypertrophy of the muscular coat so that the spasm would be the real cause of the increase in the muscle. It would seem that the condition was not congenital but acquired, and that it could not be remedied by medical means, although these should always be exhausted before resorting to surgery. Children stood operations poorly. Anesthesia in children was of the greatest importance and only the most expert anesthetists should administer anesthesia to children. Speed and thoroughness were absolutely essential to good results. Gastroenterostomy was the operation of choice up to the present time, but it was not a physiological operation. Dr. Soresi described an operation which he had devised to conserve the physiological relations of the stomach and duodenum. A piece of the ileum about three centimeters in length was severed from the rest of the intestine. With a seroserous suture close to the attachment of the mesentery on the side that naturally came in contact with the pylorus without twisting the pedicle, it was secured over the pylorus, half on the stomach and the other half on the duodenum; it was then cut longitudinally about two centimeters from the suture line, so that it became a large square piece, opening itself and showing the mucosa. The stomach and duodenum were also cut longitudinally, parallel with the seroserous suture line, leaving a margin of about two centimeters, as was done for the intestine. This incision was started from the duodenum and must be about six or eight millimeters longer than the length of the seroserous suture, extending therefore three or four millimeters on the stomach and duodenum. A through and through suture with catgut No. 0 was started alongside of the seroserous suture and continued all around, until the opening made in the stomach and the duodenum was closed. This suture done rapidly would check all bleeding. The seroserous suture was then continued all around and the procedure was completed. It was evident that between the stomach and duodenum there was now a large passage, lined with perfect mucosa, so that possible contractions would not affect the easy passage of the contents of the stomach into the duodenum. Animals showing the advantages of this method of operation were exhibited. They were in perfect condition one year after operation. In fact, they were in much better condition than dogs operated on at the same time with gastroenterostomy, with occlusion of the pylorus or leaving the pylorus patent. One of the essential points in surgery of the stomach was that the surgeon should never put his hand into the abdomen and should use as little retraction as possible, because the hand of the surgeon could not be sterilized and putting it into the abdomen caused trauma and infection which resulted in adhesions. The laparotomy incision should be made about one-half a centimeter from the linea alba between the xiphoid and the umbilicus for at least five centimeters. In stenosis of the pylorus the surgeon had to make a good permanent passage between the stomach and the duodenum. The operation resorted to in these conditions was Loreta's, which consisted in stretching the pylorus with the finger. Gastroenterostomy by the method presented was better than Loreta's operation, jejunostomy, or the different kinds of pyloroplasty. The gastroenterostomy should be a posterior one if possible. Dr. Soresi gave a lantern slide demonstration of his technique.

Dr. JAMES T. GWATHMEY said the general principle had been accepted that chloroform was not an appropriate terminal anesthetic in children under nine years of age unless accompanied by oxygen, but one could initiate the anesthesia with chloroform and then continue with other anesthetics in such a way that the anesthetic was practically devoid of danger. The American statistics of about half a million cases showed that it was satisfactory to begin with essence of orange, then follow this with chloroform for the second stage and then change to warm ether vapor. By using this sequence the patient could be brought out of the anesthetic without struggling or vomiting, but if the anesthesia were initiated with ether there would probably be both. With gas and oxygen the anesthesia could be continued with children of any age. The element of time must be taken into consideration, especially with children, and while the surgeon must do his work carefully and without hurry, he should not lose sight of the fact that the child should not be kept under the anesthetic longer than necessary. As a rough general rule it might be stated that children should not be kept under an anesthetic longer than one hour.

Dr. LEON T. LEWALD said that with reference to the question of diagnosis he agreed that repeated examinations with the Roentgen ray offered the safest and surest way of determining between spasm and true stenosis of the pylorus. There were several ways of making this distinction, but if nothing was passing through the pylorus in from one to three hours after the administration of the bismuth meal this was abundant indication for surgical interference. Dr. LeWald said he had seen gastroenterostomies in children that were successful and the children were well nourished afterwards.

Dr. WILLIAM H. STEWART said it was well known that foreign bodies passed safely through the digestive tract. The only indication for interference was when the body swallowed occasioned clinical symptoms. Undoubtedly the *x*-ray was a great help in making a differential diagnosis between pylorospasm and true stenosis, but he questioned whether if no bismuth was found passing through the pylorus after three hours that that was sufficient evidence that one was dealing with a true stenosis. Such an *x*-ray finding would have to be verified by a number of examinations. In some cases in which nothing passed the pylorus for three and one-half hours after the administration of the bismuth, a re-examination after the administration of an antispasmodic showed the bismuth passing through the pylorus. Dr. Stewart said he would like to ask Dr. Soresi if he had made any observations on the stomachs

of dogs after gastroenterostomy with reference to the emptying of the stomach. He thought about 50 per cent. of the bismuth meal passed through the pylorus and about the same amount through the stoma. With reference to what the speaker said of the susceptibility of the bone to infection, some men were saying that the death knell of Lane's plates had been sounded. He had watched Dr. Lane do his operation and the vital point in his technique was that at no time did the operator's hands come in contact with the bone.

Dr. FENTON B. TURCK said Cailli had reported the case of a child having spasm of the intestine and obstipation lasting three weeks. All the symptoms of mechanical obstructon were present. An exploratory operation showed that the condition was purely spasmodic, so the wound was closed, a systematic course of treatment was carried out, under which the child recovered. Some had ventured to state that a purely spasmodic condition would not last as long as three weeks, but the speaker had observed the condition to last for a long time in spasmophiliac children and it represented a type of fatigue, a delayed period of relaxation following contraction, which continued for a long time and was mistaken for true stenosis. It was possible for bacteria to pass from the mother to the fetus and to lodge in the pylorus and set up irritation which might result in a congenital mechanical obstruction, due to hypertrophy of the muscle and stenosing pylorus. Dr. Turch said one should be careful to avoid the mistake of making a diagnosis of real obstruction, which rarely existed.

Dr. SORESI, in closing the discussion, said that in his paper he had insisted on repeated *x*-ray examinations, and stated again that in order to be certain that one was dealing with a real stenosis of the pylorus and not with a spasm, the *x*-ray examination should be repeated several times, and that surgical intervention should not be resorted to until all medical means had been exhausted. With reference to the emptying of the stomach after gastroenterostomy in animals, if the pylorus was patent, it could be seen with the *x*-ray that a great amount passed through the gastroenterostomy opening which might be due to the fact that in the passage of food from the stomach through the pylorus it has also to pass in descending to the intestines over the gastroenterostomy opening. In animals it was seen that if the pylorus was patent the dog was in perfect shape, ate and acted normally, but if the pylorus was excluded the dog got thinner no matter what kind of food or how much was given to make it fat. This might be explained by the fact that the digestion in the stomach of the dog was exceedingly slow, and when the pylorus was excluded and the gastroenterostomy opening was made the food passed very rapidly and digestion was not complete. In human beings this did not occur because the digestion of food in the stomach was not so slow as in animals; that was not if the food or a part of it remained in the stomach a certain time after, even if it had to pass through the gastroenterostomy opening. Dr. Soresi again insisted on the avoidance of trauma through the bad practice of introducing the hands into the abdomen. He exhibited a number of specimens showing the results obtained by the reconstructon of the pylorous, and the effect of the presence of unabsorbable material in the stomach and intestine, demonstrating that when such material was present the scar tissue became much thicker.

Early Localizing Symptoms in Tuberculous Meningitis.—C. O. Hawthorne states that occasionally tuberculous meningitis has an abrupt onset, and that this may take the form either of localized palsies or of localized convulsions. Such experiences are hardly likely in themselves to suggest tuberculous meningitis, seeing that the palsies and convulsions of this disease are usually, not early, but late features of the clinical history. The diagnosis in such circumstances may review the possibility of an intracranial tumor or of an attack of encephalitis; or again, and perhaps still more likely, at least in regard to convulsions, an explanation may be hoped for in the direction of "reflex irritation" arising from such influences as troublesome dentition, digestive disturbances, intestinal parasites, and so on, such a view of the position being facilitated, perhaps, by the temporary character of the convulsive or paralytic events. There would seem, therefore, to be some practical value in illustrations of the statement that a localized paralysis or a unilateral convulsive seizure may mean the clinical beginning of tuberculous meningitis.—*British Journal of Children's Diseases.*

Therapeutic Hints.

An Antiseptic Powder for Infected Wounds.—Mouchet and Malbec use a powder prepared as follows: Five grams of iodine are dissolved in 100 c.c. of ether and then 100 grams of powdered red cinchona are added. The resulting mass is triturated until the ether is completely evaporated. The powder is then passed through a fine sieve. It has a pleasant odor and costs less than one-sixth of the price of iodoform. The authors claim that its antiseptic power is equal to that of iodoform. A powder with 10 per cent. of iodine is indicated in gangrenous wounds.

Pyorrhea Alveolaris.—Cryer recommends the following as an antiseptic mouth wash:

℞ Acidi borici, ʒj.
Phenolis, ♏xij.
Glycerini, f ʒj.
Olei menthæ piperitæ, ♏vj.
Aquæ destillatæ, q.s. ad f ʒvj.

Sig.: Use as a mouth wash in full strength or dilute with an equal quantity of water.

Dandruff, Seborrhea of the Scalp.—Schamberg strongly recommends the use of sulphur ointment two or three times a week and on alternate nights the use of a lotion of resorcin. The ointment prescribed is:

℞ Sulphur praecip., ʒj.
Adipis benzoat. ʒij.

The lotion:

℞ Resorcini, ʒij.
Spirit vini rect.,
Aq. cologniensis,
Aquæ, āā fl ʒij.

A dram of glycerin may be added if the scalp becomes too dry. If more stimulation is desired 30 grains of β-naphthol should be added to the lotion.

Pruritus Vulvæ in Pregnancy.—Kelly tells of Ashwell's and Meig's recommendation of the following prescription for the relief of pruritus vulvæ, especially in pregnant women:

℞ Sod. biborat., ʒss.
Morph. sulphat., gr. vj.
Aq. rosæ dest., ʒviij.

M. Sig.: Apply three times a day to the affected parts with a piece of lint, after first washing with tepid water and soap and then carefully drying the parts.

Flaischler recommends the local application of a 20 per cent. or even a 50 per cent. solution of silver nitrate.

Suprarenal Extract for Intractable Hiccough.—Segal reports a case of hiccough that lasted for eleven days. It began three days after an attack of renal colic. Large doses of bromide, chloral, chloroform, and cocaine were in turn given, but without bringing relief to the patient, who suffered great pain because of the violence of the hiccough. Finally adrenalin was given in a dose of 10 drops of a 1-1000 solution, when the hiccough immediately became less frequent and on a reptition of the dose ceased entirely and did not recur.—*Journal des Praticiens.*

Bismuth Carbonate for Chronic Colitis.—Sandstein, in a persistent case of chronic colitis, which resisted all other medicinal and even surgical treatment, obtained relief by giving half ounce doses of bismuth carbonate twice daily, giving in all five ounces by weight.—*The New Zealand Medical Journal.*

OBSERVATIONS ON PANCREAS STONE COLIC.

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

THE occurrence of pancreatic stones is generally considered rare, and still rarer their recognition during life. As I have had the opportunity to observe two cases of this disease, I deem it of interest to discuss the subject.

The literature on this subject up to 1902 is contained in an article by F. P. Kinnicutt.[1] In it there are short reports on cases of pancreatic lithiasis, described by Capparelli,[2] Lancereaux,[3] Leichternstern,[4] Lichtheim,[5] and Minnich,[6] and a detailed description of a new case observed by Kinnicutt himself. The latter case was in a female patient, 42 years old, who at first was thought to be suffering from gallstones, but later was considered a case of pancreatic lithiasis on account of recovery in the stool of small stones (the size of a pea), consisting principally of calcium phosphate and carbonate, without a trace of cholesterin or bile pigment. The case is of additional interest, as beside the pancreatic stone gallstones were present. For after a severe attack, associated with icterus, the patient passed a true gallstone containing 92 per cent. of cholesterin by analysis.

The latest literature may be readily grouped into three classes: (1) Cases in which pancreatic stones were found at autopsy; (2) cases in which pancreatic stones were found at operation; (3) cases observed clinically, (*a*) without, (*b*) with the presence of undoubted pancreatic stones.

I will now review the literature according to this grouping.

Allen[7] reports a case of pancreatic calculi. Patient, female, 30 years old, suffered first from jaundice, later from frequent attacks of epigastric pains appearing in the left hypochondrium, and lumbar region in biweekly intervals. At first there was no sugar, later sugar appeared in the urine for a short while. There were great emaciation, slight fever, and at times leucocytosis. An exploratory incision revealed the presence of two pancreatic cysts with calculi. Patient died five days after the operation. The autopsy showed a greatly atrophied pancreas and calcareous particles throughout its duct. At the orifice of Wirsung's duct there was a stone the size of a small marble, almost entirely obstructing its lumen.

Phillips[8] describes a case of chronic pancreatitis with calculi. Patient suffered at first from chronic jaundice, the liver was found enlarged and the gall-bladder could be palpated. At operation an enlarged gall-bladder was found, but no stones. The pancreas was enlarged and hardened, the head compressing the biliary duct. Patient felt better for a while, although the icterus remained; then she developed sugar in the urine and began to lose in weight. Later on she became comatose and died. At autopsy fibrosis of the pancreas and numerous calculi were discovered.

Atkinson and Hirsh[9] described a case of pancreatic lithiasis in a man, who, six years previously had a fall from a horse followed shortly by a hemorrhage from the stomach. Four years later he began to suffer from epigastric cramps and nausea; at that time an elongated hard mass about 10 cm. in length and one cm. in width could be felt in the epigastrium, which was thought to be connected with the pancreas. The urine at that time was normal. About one year later sugar occurred in the urine and all the symptoms of a severe diabetes mellitus appeared, also fatty stools and emaciation. During the course of the disease the diagnosis of a severe pancreatitis was made. The patient died soon after and the autopsy revealed a sclerosis of the pancreas with a calculus in the duct of Wirsung.

Rindfleisch[10] observed three cases of pancreatic stones in 2,000 autopsies. In one case (a widow) severe colic with jaundice and swelling of the liver were present followed by diarrhea, slightly increased temperature, and peritonitis with fatal outcome. The autopsy showed a pancreatic calculus the size of a pea obstructing the duct completely. The same stone also pressed upon the common duct, causing occlusion with stagnation of bile, subsequently cholecystitis and perforation.

In the second case, also a woman, diabetes had been present for three years, together with tuberculosis of the lungs. There were no colics and no diarrhea. The patient died in an attack of sudden heart weakness. At autopsy a very atrophic and hardened pancreas was found. The parenchyma was traversed by very tough white connective tissue strands; in the head as well as the tail of the pancreas a stone, the size of a cherry, was found. These stones were white and somewhat hard.

Keuthe[11] describes a case of atrophy of the pancreas with the formation of a concrement in this organ. During life it was possible to make the diagnosis with some certainty of chronic pancreatitis; steapsin was absent in the stool, steatorrhea and a positive nuclear test were present, sugar was also occasionally found in the urine. The patient died of pneumonia and the post-mortem showed a complete atrophy of the pancreatic tissues and some yellowish white concrements the size of lentils, in the pancreas.

Pfoerringer[12] published a case of pancreatic stone. The patient was a man suffering from severe colics in the left side of the abdomen, which were

thought to be due to nephrolithiasis. *X*-ray examination showed a marked shadow on the left side, but somewhat nearer to the vertebral column than is usual for kidney stones. The patient died and a pancreatic calculus was found at the post-mortem.

Heiberg[13] reports two cases of pancreolithiasis, in which during life severe diabetes mellitus was present; in one case there were also fatty stools. In both pancreatic concrements were found at autopsy.

Ruth[14] describes the following case: the patient, a woman, was suffering from severe colicky pains, which were considered due to gallstones. At operation liver and gall-bladder were normal, the pancreas, however, was studded with small calculi; the largest being over 2 inches in length and weighing 280 grams. Ruth was successful in removing most of the stones and by draining of the pancreas in curing the patient.

Link[15] reports a case of chronic pancreatitis with calculi. Patient, female, suffered from attacks of pain centering on the left side just under the ribs, and was tender there constantly. No diarrhea; no free fat in the movements. Pain somewhat relieved in lying. The urine was free from sugar or albumin. An exploratory laparotomy showed a symmetrically enlarged pancreas. The head was as large as a man's fist, and the body was the size and shape of a man's wrist. It gave the same sensation to the touch over its entire extent as of a bag filled with sand. Link opened the dilated duct of Wirsung, which was found to be filled with small facetted stones along its entire length. The stones were removed and the duct drained. Patient made a good recovery.

Zesas[16] reviewed thoroughly the literature of pancreatic stones (comprising 70 cases) and came to the following conclusions: Glycosuria and steatorthea are frequent and constant symptoms of pancreas stones. Jaundice may be present or absent. Attacks of colic in the upper abdomen and the finding of concrements in the feces belong to the initial stage.

Skaller[17] reports four cases of his own of pancreatic calculi, one of these, occurring in a woman, is described in more detail. Numerous elongated concrements, consisting mainly of calcium salts were found in the stool. Skaller considered the prognosis favorable.

Friedman[18] published a case of chronic pancreatitis, probably caused by pancreatic stones: there were disturbances of the pancreatic function (lack of trypsin and very little steapsin in the feces), severe colic-like pains in the left abdomen, frequently sugar in the urine, and beside that a shadow on the *x*-ray plate in the region of the pancreas. The patient was operated upon, the pancreas was laid open, and the ducts were thoroughly explored, but beside a chronic pancreatitis, no concrements were found. The patient died shortly after the operation and even at the autopsy no stone could be found in the pancreas.

Glaessner[19] described four cases of pancreolithiasis; in two the diagnosis was assured, in these after the attacks concrements were found in the stool the size of a lentil and consisting of calcium carbonate. Alimentary glocosuria is frequently present. Therapeutically Glaessner recommends oil with large quantities of akaine fluids. He believes the affection to be of rather frequent occurrence.

Dowd[20] recently described a case of pancreatic abscess with numerous calculi. About thirty small concrements of pea size were found in the abscess cavity. They consisted principally of cholesterol.

From this literature we can see that pancreatic calculi are rare, but occur more frequently than was thought formerly. I will now give a detailed history of my own two cases.

Case I.—*Probable Pancreolithiasis.*—September, 1904. Henry P., 44 years old, has been suffering for a year from severe epigastric pains, occurring periodically, and associated with dyspnea. The attacks appeared without any known reason and disappeared after 1 or 2 days, the patient then feeling fairly normal. The attacks occurred every 2 or 3 months. During the attack there were considerable prostration, aversion to food, sometimes vomiting. Generally there was no fever. The patient was examined by me for the first time shortly after an attack. The thoracic organs were normal. Palpation of the abdomen revealed nothing abnormal. The only definite sign was an increased tenderness on deep pressure in the epigastrium. The urine showed the presence of about 1 per cent. sugar (fermentation test) and no albumin. Examination of the stomach contents showed normal conditions. In one week the sugar disappeared even with a liberal carbohydrate allowance.

In December of the same year the patient had another attack of a similar nature (epigastric colic, dyspnea, and fright.) The urine voided during the attack contained sugar, but no bile pigment. Morphine relieved the attack quickly and the patient resumed his work.

In February, 1905, he had another attack, accompanied this time, however, by a severe chill. The disease ran a more severe course, fever was present and on the second day of the trouble slight jaundice developed. The urine contained sugar and a trace of bile. The liver was slightly swollen. Four to five days later the pains suddenly subsided. A few days later the urine was free from sugar and the patient has been well since, without having had any more attacks.

As to the diagnosis of this case, the occurrence of the sugar in the urine during the attack made an affection of the pancreas very likely; the localization of the pain and the dyspnea also favored this view. The abrupt periodical occurrence and the sudden disappearance of the symptoms may be ascribed to a mechanical obstruction (calculus). The diagnosis of pancreolithiasis is also strengthened by the fact that the patient after this last and severest attack never had another one. Probably the stone was passed and thus complete recovery resulted.

Case II.—Mrs. G. A. R., 37 years old, suffered for the last nine years with distress after meals and periodically recurring colic-like pains in the epigastrium. Six years ago she was jaundiced and ill in bed for six weeks. She recovered but continued to suffer at frequent intervals from epigastric distress and colicky attacks. Appetite was fair, bowels slightly constipated.

December 3, 1914. *Present Condition:* Physical examination of the thorax revealed nothing abnormal. Stomach was slightly dilated extending to about two fingers' widths below the navel. The right kidney was movable in the first degree. There was no distinct pain on pressure anywhere in the abdominal cavity. The gastric contents on December 11, 1914, one hour after an Ewald test meal showed the presence of HCl and an acidity of 72, no blood. The duodenal bucket, given December 12, revealed permeability of the pylorus (bile stain from 60 cm. on), no blood stain. The digestive test capsule, given on December 14, reappeared after 44 hours; every thing had disappeared except the thymus; nuclei were present. Neither in the gastric contents nor in the feces was any trace of blood ever found.

On December 16 a calculus of the size of a medium-sized pea, not quite round, somewhat facetted, of a dirty whitish appearance, and with a roughened surface, was found in the stool. This calculus was handed for examination to the chemical laboratory of Dr. F. Sondern. His report, for which I am greatly indebted to him, was as follows: "Half of the stone was taken for analysis: weight 0.05 gram. Composition: chiefly calcium car-

bonate with traces of organic matter. Cholesterin and bile pigments could not be demonstrated." (See Figs. 1 and 2.)

December 18 the duodenal contents were examined after tea and sugar: golden yellow clear, alkaline;

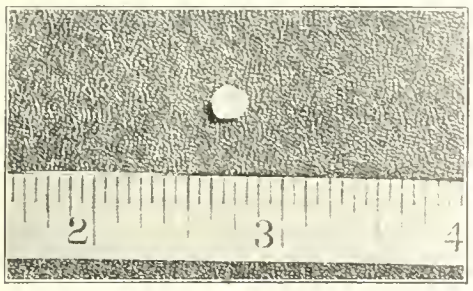

FIG. 1.—Pancreatic stone found in the stool; natural size

trypsin = 3 mm., steapsin = 4 mm., amylopsin = 8 mm. Patient was given alkalies and advised to try medical treatment before underoging an operation, but she was also told, that in case there should be a severe attack to return to the hospital and if necessary, be operated upon. Her condition not improving and the attack recurring in a more severe type, patient returned to the hospital on January 28, 1915.

In view of the persistent attacks and the absence of any signs of ulcer of the stomach or duodenum, the diagnosis of a calculus presumably from the gall-bladder was made. The chemical analysis of the stone found in the feces, however, showed an entire absence of cholesterine or biliary pigment and showed that it chiefly consisted of calcium carbonate. This pointed against a biliary and rather for a pancreatic calculus. In harmony with this the duodenal contents obtained showed clear bile while in cholecystitis due to gallstones it is usually turbid. The diagnosis therefore before operation was that of pancreatic stone. An operation was now advised and performed by Dr. Stetten on January 29, 1915. At the laparotomy no signs of any abnormality of the pylorus or duodenum were found. The gall-bladder was enlarged, but normal in appearance and contained no concretion whatever. The pancreas was also somewhat enlarged, but no stones could be palpated by the search. A cholecystostomy for drainage of the gall-bladder was done, and the patient made an uneventful recovery, and remained free from attacks up to the present. The findings at the operation and the subsequent course tend to substantiate the diagnosis of pancreatic calculus.

Epicrisis.—If we study the two cases just described we may gather the following points as to

Diagnosis.—Colic-like pains, occurring periodically in the epigastrium, associated with a transient glycosuria are probably caused by a pancreatic stone. The sudden disappearance of the symptoms favors the assumption of the passing of the stone.

The occurrence of a calculus in the feces, consisting mainly of calcium carbonate and phosphate without cholesterin or bile pigment, points to the

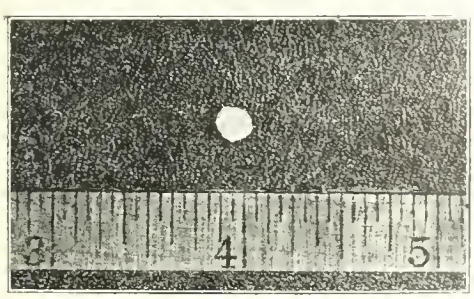

FIG. 2.—Transverse section of the stone shown in Fig. 1, natural size.

pancreatic origin of the stone. At the commencement and for a long time to come the process may not at all interfere with the functions of the pancreas. Only later the presence of a calculus may lead to changes of the pancreatic tissue, which again causes an impairment of the function of this organ. One can see from this what is also clinically confirmed, that a disappearance of the pancreatic function belongs to a later stage of pancreolithiasis and cannot be made use of in any early diagnosis.

The occurrence, however, of sugar in the urine during an attack, is of prime importance, although an absence of this symptom would not militate against the diagnosis of pancreatic stone.

Treatment.—As in all other diseases an early diagnosis offers the best opportunity for successful treatment. Just as in gallstone colic rest during and immediately after the attack is of most importance. The patient is kept in bed, placed upon a light diet, warm applications are made to the abdomen and if the pains are severe, opium or atropine or both may be given.

Shortly after the attack frequent small meals and the drinking of alkaline waters are indicated. If these measures should not be successful and the attacks become more frequent or if they become more severe and are attended with a slight rise of temperature, an operation should be advised in order to examine thoroughly the gall-bladder and pancreas. If a stone is found it ought to be removed. If this is not the case—frequently with small stones it is impossible even with the pancreas directly under our fingers to feel them—drainage of the gall-bladder should be done. This must also be done when stones have been found and removed, as one cannot be sure that small stones have not remained hidden. The drainage of the gall-bladder exerts a beneficial effect upon an existing pancreatitis, which we generally find associated with the calculi. Through free drainage the liver and pancreas are eased and the latter organ returns to normal activity.

IMPOTENCE IN THE MALE.

BY MAX HÜHNER, M.D.,

NEW YORK.

CHIEF, GENITO-URINARY DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY, NEW YORK CITY; MEMBER AMERICAN UROLOGICAL SOCIETY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

Definition.—Impotence in the male is that condition in which the man is unable to perform the sexual act. It may be either complete or partial. In the former he is absolutely unable to perform the act, while in the latter, he may still be able to have a more or less complete erection, but either the erection is so weak that it subsides at the moment of intromission, or even before intromission, or, in addition to this weakness, there may exist such a hyperirritability of the parts or sexual centers, that the entire process of erection and ejaculation lasts but a very short while and is finished at the moment of intromission, or a very short while after intromission or even before the penis has had an opportunity to enter the vagina.

Impotence in the male must be strictly differentiated from sterility in the male. In sterility there is an impossibility of impregnating the female, while in impotence there is an impossibility of performing the sexual act. The sterile man, is not necessarily impotent. He may be fully able to properly perform the sexual act, but on account of an old double epididymitis with occulsion of both vasa, not one drop of his testicular secretion can reach his penis. In bad cases of hypospadias and epispadias the man may have proper erection and ejaculation, but, on account of the abnormal opening of his urethra, not one drop of his semen enters the vagina, and sterility is the result. On the other hand it is also possible for a man who is partially impotent not to suffer from sterility. He may have premature or very rapid ejaculation and only be able to deposit his semen at the very entrance of the vagina, without even real intromission, and still pregnancy may result. As a general thing, however, the impotent man is also sterile, inasmuch as (except in very exceptional cases) he is unable to deposit his semen deep enough into the female genitalia to cause impregnation.

I believe the old classification of impotence into impotentia coendi, and impotentia generandi, the former designating impotence of coition and the latter, impotence of impregnation, has been the cause of much confusion. It is far better to limit the term impotence to define impossibility of performing the sexual act, and sterility to impossibility of impregnation.

Impotence may be classified according to its pathology into (1) Organic Impotence, (2) Functional Impotence, and (3) Psychic Impotence.

I—ORGANIC IMPOTENCE.

Definition.—Is that condition in which the impotence is due to some anatomical defect in the sexual organs.

Etiology and Pathology.—Any condition which may cause a lack of development of any portion of the sexual apparatus, or an atrophy or degeneration of these parts is an etiological factor in this form of impotence. Among such conditions may be mentioned mumps, which in bad cases may cause a complete atrophy of both testicles so early in life as to preclude the development of sexual powers. Injuries or other conditions which may result in complete castration before puberty will also interfere with the development of sexual sense and power. Lack of development or absence of the penis, either congenital or by destruction of this organ through injury or disease must result in impotence, although the sexual desire may still be present. In certain forms of spinal syphilis as well as in locomotor ataxia the erection centers may be completely destroyed and impotence will follow. Injuries to the spinal cord may cause impotence, either by direct destruction of the erection center or by destruction of those fibers which convey the impulses to and from these centers to the peripheral organs. In the same way injuries to the cerebrum may likewise cause impotence. Severe injuries to the urethra may result in such distortion and shortening of the urethra, that it is impossible to stretch in erection, resulting in curvature of the penis and impotence. Cicatricial contractions of the tissues of the penis, as the result of burns, or other traumas may also mechanically interfere with erection.

It must however be emphasized that while complete absence of the penis must of necessity lead to impotence, yet a small undeveloped penis does not *necessarily* lead to that result. There are many cases on record in which men with almost rudimentary penes were able to perform the sexual act more or less properly. The same may be said of hypertrophy of the penis. There are indeed very few penes, no matter how large, in which intromission is not possible. Sturgis[1] gives an extreme case mentioned by Hyrtl, of a Swiss smith whose penis was the size of a child's body. Of this case Sturgis remarks "Clearly such an unlucky wretch would be compelled to a life of celibacy, for no mortal vagina would be capable of receiving such a membrum virile." It is also remarkable how much of the penis can be destroyed by ulceration or other causes without resulting in impotence. Among other curiosities which may have that effect may be mentioned peno-scotal fusion, and bifid penis, while neoplasms of the penis may, from their size, render the person impotent. Plastic exudates either in the corpora cavernosa or corpus spongiosum may also interfere with erection. Shortness of frenum has likewise so interfered with erection that impotence resulted until relieved by operation.

Among other conditions interfering with intromission may be mentioned enormous hydrocele, large scrotal hernia and elephantiasis. In these conditions the penis may be so enveloped by the surrounding parts that it appears absent, and cannot protrude enough for intromission even in erection. After gangrene of the penile integument or after destruction of portions of the penis from chancroidal ulcerations, scarring and contraction may result to such an extent as to interfere with erection. Among the rarer conditions causing organic impotence may be mentioned horny growths of the penis, elephantiasis of the penis and scrotum, prepucial calculi, ossification of the penis, and lastly fracture of the penis, either as a result of coitus or of "breaking" a chordee.

Walsh[2] reports an unusual condition causing impotence in the male. In these cases erection was normal but there was absolutely no ejaculation. Nocturnal pollutions, however, did occur, and massage of the prostate produced a normal appearing fluid which contained actively motile spermatozoa. On attempting to introduce the posterior urethroscope an obstruction was experienced in the posterior urethra. The posterior urethra was dilated by sounds until the urethroscope could be introduced. It was then seen that there had previously existed a band of tissue connecting the two ejaculatory ducts, which was torn by the sound dilatations. After this the patient became perfectly normal.

The explanation given by Walsh is that during erection, the posterior urethra, or at least that portion adjacent to the ejaculatory ducts should be capable of distention to receive the contents of the ducts. On account of the presence of the band of tissue, however, this was impossible. The fluid could not enter the urethra and ejaculation was impossible. During sleep, however, when the penis is not at all or only partially erected, there is no tension put on the urethra causing the mouths of the ejaculatory ducts to close, and consequently the seminal fluid escapes easily. The same held good in massage of the prostate.

Horseback riding as well as bicycle riding may cause impotence if done excessively and for a prolonged period of time. Moderate exercise in this regard has no such effect.

Symptoms.—The chief symptom is the impotence itself. In many cases partial erection can take place, and in some cases erection takes place but is exceedingly painful. As a result of any form of impotence there often follow a whole train of nervous symptoms, in some cases bordering on insanity and not infrequently leading to suicide. But as these symptoms are common to all forms of impotence, whether organic, functional, or psychic, they will be described later on.

Diagnosis.—The main point in the diagnosis is to find the original cause, for after all, impotence is but a symptom of some other disease.

Prognosis.—This depends upon the etiological factor, and the possibility of removing the impediment by operation or other means. Many of the causes just mentioned are very easily remedied by operation, while others are clearly beyond our control.

Treatment.—A glance at the various etiological factors will indicate the method of treatment in many of these cases. One point should be emphasized, however, in the management of cases with small or rudimentary penes. For some of these cases, ingenious apparatus have been invented enabling the penis to enter the vagina, especially if the woman be instructed to take an astringent douche before coitus. It has also happened that after frequent coitus with the aid of such apparatus, the penis has actually increased in size and developed sufficiently for coitus without any artificial aid.

II—Functional Impotence.

Definition.—Functional impotence is that form of impotence in which there exists no *gross* pathological change in the structure of the sexual apparatus, but in which the mechanism of copulation is disturbed through an interference with the function of the sexual centers of the nerves and peripheral endorgans.

In this class of cases, there is found neither the absence of important organs nor the marked pathological conditions mentioned under organic impotence. Generally speaking, the sexual organs are sound. I have emphasized the word "gross," to indicate that the condition is not without a pathological basis, and that, in a not infrequent number of cases, the endoscope will reveal areas of congestion, inflammation or even erosions in the posterior urethra, and in many of them an examination will show congestion of the prostate and seminal vesicles. The condition must be considered functional, however, because these lesions do not act by imposing a mechanical impediment to either ejaculation or erection, but act purely reflexly upon the sexual centers.

Impotence is physiological before puberty as well as in old age. It may also be considered physiological after a normal coitus, although some men are able to repeat the act many times.

It must be emphasized, however, that Potency or Sexual Vigor is a *relative* term, and that there are some men who can indulge in coitus every night and keep this up for a very long time, while others, can only indulge once or twice a week. A man belonging to the latter class would by no means be considered impotent or suffering from sexual weakness. We must, therefore, take the entire history of the case into consideration before deciding whether a man is losing his sexual vigor.

Etiology and Pathology.—The normal act of coitus consists in the following sequence of events, and in the harmonious relationship of the various factors. In the first place there must be the libido, or desire for sexual intercourse, then there must be the erection of the penis, then ejaculation and finally the orgasm. The absence, or disturbed relationship of any of these factors, constitutes impotence, either partial or complete. Moreover, not only must the normal sequence of events occur, but also the relative time for each factor must be observed for normal coitus. Thus, if ejaculation comes too quickly, before erection is complete, or too slowly, that is long after erection has subsided, or if erection does not last long enough, or if the whole process of coitus goes very quickly, or any other condition in which the time allowed to each factor is relatively out of proportion, impotence may be said to exist.

In order to understand the pathology of organic impotence, as well as the influence of various etiological factors in the production of the same, it is necessary to have a clear idea of the mechanism of normal coitus. This will be considered under two heads, first the mechanism and sequence of events as they take place in the endorgans (*i.e.* the testicles, epididymi, vas, seminal vesicles, ejaculatory ducts, prostrate and penis) and secondly, the sequence of events in the sexual centers and nerves.

Mechanism of Coitus in the Endorgans.—As soon as the libido is aroused, either by the sight or contact of a woman, or from peripheral irritation of the penis, an impulse is sent to the erection center in the lumbar portion of the spinal cord, which arouses it into activity. The center, now aroused, sends impulses to the arteries and muscular structure of the penis. In the quiescent state, the arteries of the penis are in a state of contraction, allowing no more blood than is necessary for nourishing the parts. The musculature is also in a contracted state thus obliterating all trabeculation. The impulses which are sent out from the erection

center are vasodilator in character, thus allowing the arteries to dilate and fill up with blood; they have also the effect of relaxing the musculature, and so causing the formation of large trabecular spaces. As a result, the corpora cavernosa become engorged with blood. The muscles surrounding the penis, however, are thrown into contraction, which has the effect of compressing the veins of the penis, and the resulting congestion adds still further to the engorgement of the parts. The fibrous investment of the penis is put on the stretch by the increase in volume of the organ, and this also adds to the compression of the veins and the consequent engorgement of the penis. The influx of blood, however, has more to do with erection than the compression of the veins; this is proven by the fact that in priapism, which may continue for a very long time, sometimes for days and even weeks, no gangrene results.

As soon as the organ becomes rigid, the action of its suspensory ligament aided by the erector penis and the accelerator urinæ muscles causes it to become elevated. Finally all the perineal muscles come into play to complete the erection, and now the organ is hard and tense. The testicles at the same time are drawn close to the abdomen through the contraction of the dartos and the muscular fibers of the cord.

As a result of the active congestion, the mucous glands of the urethra pour into the urethra an alkaline secretion to neutralize any acid urine which may have been left therein, and which would be inimical to the vitality of the spermatozoa.

As a result of the muscular action upon the testicles, aided by the peristalsis of the musculature of the epididymis and the vas, the spermatozoa are pressed out of the epididymis into the vas and into the ampulla.

As coitus proceeds the contents of the seminal vesicles are squeezed by muscular action into the ejaculatory ducts, the muscles of the prostate also contract, squeezing out the prostatic secretions, and at the height of the orgasm the contents of the seminal vesicles mixed with the spermatozoa which have just been extruded from the testicles, are pushed through the ejaculatory ducts into the posterior urethra, where they mix with the prostatic secretion, and the entire product, the semen, is driven from the bulbous urethra through the penis by the contraction of the entire perineal group of muscles. The squeezing of the contents of the seminal vesicles plus the testicular contents into the posterior urethra, causes the extreme of pleasurable feeling known as the orgasm.

It may be noticed that in the above description of the physiology of coitus, I have *not* mentioned that the semen, after it has reached the posterior urethra, is prevented from going into the bladder by the erection of the verumontanum, which by its erection closes off the posterior urethra from the bladder. This statement has been passed on from, I do not know how many years back, until the present time, and may be found even in some of our latest text-books. Like so many statements, it has simply been copied from one work into another without investigation or challenge.

Since the advent of modern improved posterior urethroscopes, however, it has been noticed that in many cases the verumontanum may be exceedingly small; in fact I have seen it in some cases no bigger than a pimple, and nevertheless no interference with the act of coitus is experienced. Moreover, Rytina[3] has reported a series of casees, in which for various reasons he had removed the entire verumontanum, without any sexual difficulty being experienced by the patients.

Nervous Mechanism of Coitus.—In the description of the sequence of events which take place dur-

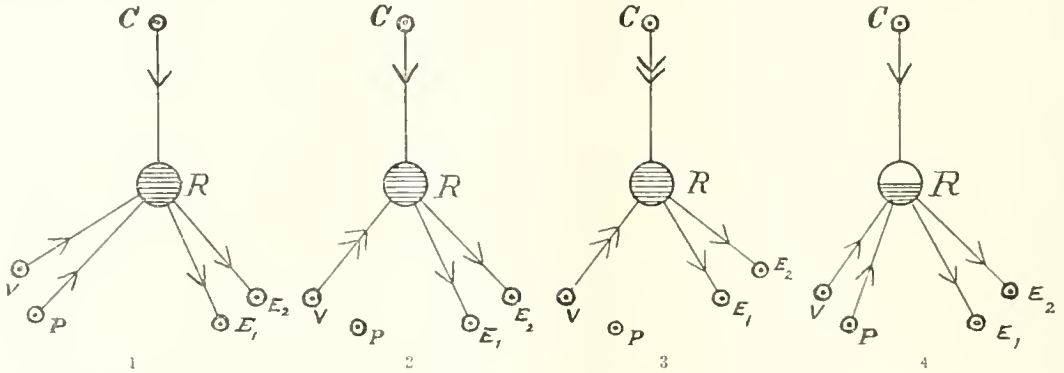

Fig. 1.—Diagrammatic scheme of the nervous mechanism of normal coitus, impotence and pollutions. *C*, cerebrum; *R*, erection center; E_1, sympathetic ejaculation center (which causes the expulsion of the secretions of the sexual glands); E_2, spinal ejaculation center (which controls the striated muscular fibers); *P*, glans penis; *V*, seminal vesicles. The single arrow indicates an ordinary impulse; the double arrow, a very strong impulse. The transverse lines in *R*, in 1, 2, and 3 indicate that *R* sends out impulses to E_1 and E_2 *only* after having been completely filled up with impulses, while in 4, we see that *R* sends them out before it is completely filled up with them.

ing normal and pathological coitus in the sexual centers and nerves, I have closely followed that given by Groag[4] as being of especial clearness.

We may represent the various conditions diagrammatically as follows (Fig. 1, Nos. 1-4): From C (cerebrum, *i.e.* libido) impulses are sent to R (erection center) which sends them to the dilator nerves until complete erection results (*i.e.* dilatation of blood vessels of penis, etc.). Now R receives from P (glans penis during friction) continuous new impulses which serve to strengthen and keep up the erection. Besides sending the receiving impulses to the dilator nerves, R has also the function of keeping back a part of the impulses it receives until the cells of the erection center are filled to their utmost tension (Reitzspannungsvermögen) and then only to send the impulses to E_1 (sympathetic ejaculation center, which causes the expulsion of the secretions of the sexual glands) and also to E_2 (spinal ejaculation center, which controls the striated muscular fibers). The impulses that come from P to R (through friction of the glans penis) may be weaker, in proportion as the impulses that come from V (distended seminal vesicles) are stronger. In other words, with markedly distended seminal vesicles, we can get normal coitus even if

there is less friction of the glans penis, for enough impulses are coming from the seminal vesicles to fill up R. As soon as R is so filled up with impulses from C, P and V that they overflow to E_1 and E_2, ejaculation occurs.

We may now briefly describe the nervous mechanism of normal coitus according to the above diagrammatic scheme, and later on the pathology of impotence according to the same scheme. The seat of the libido is in the cerebrum, and it may be aroused by the sight of a woman, contact with a woman, or by spooning, erotic literature, or through any of the senses and in numerous other and different ways. Once the libido is aroused, and the person is prepared for normal coitus, an impulse is sent from the cerebrum (C) to the erection center (R) in the lumbar enlargement of the spinal cord. This center sends impulses through the dilator nerves to the penis, as a result of which impulses, the penis becomes engorged with blood and erection occurs as previously described. As the penis enters the vagina, the friction of the glans penis (P) sends additional impulses to the erection center (R). The erection center (R) is also getting impulses from the distended seminal vesicles (V). In the normal condition of affairs, it is only when the erection center (R) has been completely filled up with these impulses from the cerebrum (C), the penis (P) and the seminal vesicles (V) that it sends out impulses to the ejaculation centers (E_1 and E_2) and allows ejaculation to take place. In other words the erection center (R) has two functions, first, to receive impulses from the cerebrum (C), the penis (P) and the seminal vesicles (V), and secondly, to hold back these impulses till the proper time and then send them to the ejaculation centers (E_1 and E_2), so that ejaculation should come just at the proper time and not too soon.

I have gone somewhat minutely into this diagrammatic description of the nervous mechanism of normal coitus, because it is only by having a clear idea of this mechanism that we are enabled to understand the pathology of impotence. We will now take up the various etiological factors, and show how they cause impotence, by disturbing one or more of the functions of the above factors of normal coitus, or by disturbing the relationship of the various factors. The various etiological factors to be discussed will be, acute impotence from excessive coitus, coitus interruptus (withdrawal), masturbation, sequelæ of gonorrhea, ungratified sexual excitement (prolonged spooning, etc). The pathology of many of these etiological causes will be found to be very similar.

Pathology of Impotence from Excessive Coitus.—This is the simplest form of functional impotence and consists in an exhaustion of the erection center (R). If, shortly after a completed coitus a repetition of the act is attempted, stronger excitation is necessary to accomplish erection, and still stronger and more intensive to produce ejaculation. With every repeated attempt at coitus, the necessary increase in excitation rises in proportion with the number of attempts. This can be readily appreciated from our diagrammatic scheme. After one or several attempts at coitus, the seminal vesicles are empty, and the erection center (R) thus receives no impulses from them (V), the friction of the glans penis during coitus is also less and less powerful, and so few impulses come from there (P), and the erection center (R) must therefore depend almost entirely upon the impulses it receives from the cerebrum (C) in order to cause erection and also in order to get enough impulses to become distended so that it can send them out to the ejaculation centers (E_1 and E_2) for ejaculation to take place. The erection center (R) is now in a state of absolute exhaustion, and needs a certain length of time to recuperate. After this recuperation, everything is normal again. This is the acute form of impotence in a normal person. Finally the most intensive excitations fail to cause an erection and naturally also an ejaculation.

Pathology of Coitus Interruptus.—In the normal condition of affairs, as soon as the libido has been aroused, and the impulse has been sent from the cerebrum (C) to the erection center in the lumbar enlargement of the spinal cord (R), thus arousing it into activity, there occurs a normal working hyperemia of this center. This working hyperemia is being increased during coitus by continuous stimulation of impulses from the glans penis (P) and seminal vesicles (V). As soon as this center has been stimulated to its maximum, it sends its impulses to the ejaculation centers (E_1 and E_2), ejaculation takes place, and with this event, there results a diminution and final disappearance of the hyperemia of the erection center. Normally, there now ensues a condition of rest for several days and the center has plenty of time to recuperate. Sexual intercourse is not generally indulged in for several days, and the erection center is not bothered with stimulating impulses from either the cerebrum, seminal vesicles or other sources. (In this description I leave out of account the increased sexual activity which follows the first months of wedded life). Normally, also, the same condition holds good in the endorgans. During coitus, the seminal vesicles which were distended empty themselves more or less completely, the prostatic urethra, which during coitus is also hyperemic, becomes deplethorized with the normal act of ejaculation, and the parts soon regain their normal condition of blood supply.

What is the condition of affairs in coitus interruptus? The following description of the pathology does not apply to one single act of withdrawal, but only to those cases where the practice had been kept up for a long time, months or years.

With the interruption of the act of coitus, ejaculation is incomplete, the erection center (R) is not thoroughly deplethorized, on account of the incomplete ejaculation. It thus remains more or less hyperemic. The seminal vesicles do not so compeltely empty themselves as in normal coitus, and they consequently become distended much sooner than after a normal coitus, and the desire for coitus is thus experienced much earlier than after a normal coitus. The hyperemic condition of the prostatic urethra, which under normal conditions disappears with the complete ejaculation, remains more or less in part, and after the practice had been kept up for a long time, a condition of chronic congestion of these parts supervenes. The frequent distention of the seminal vesicles leads to increased desire for coitus, and increased coitus still further keeps up the hyperemic condition of the erection center, leaving less time for it to recover itself. The chronic congestion of the prostatic mucous membrane, has the effect of continually sending impulses to the sexual centers, even in the absence of coitus, and thus the hyperemic erection center is being constantly bombarded with impulses until

finally it is at first in a state of hyperirritability and finally of exhaustion. While in a state of hyperirritability, the slightest impulse it receives from the cerebrum, at the very commencement of coitus, causes it to respond so rapidly that it at once sends the impulse to the ejaculation centers and ejaculation takes place, at the very commencement of coitus, just as the penis has entered the vagina (rapid ejaculation) and in a later stage, even before the penis has had an opportunity to enter the vagina (premature ejaculation). In other words the center has lost its power to hold back the impulses till the proper time. This is graphically illustrated in Fig. 1, No. 4. Finally the center becomes completely exhausted, and fails to respond to any stimulus either from the cerebrum or other sources; it refuses to send out any impulse at all, and we thus get, as a final stage, not only no ejaculation, but also absence of erection.

It is very interesting, if we take a careful history of one of these cases, how the symptoms follow exactly the pathology just described. We first get a history of rapid ejaculation, less and less time is consumed in the coital act, the erections may however still be strong; then we get premature ejaculation, next a weakness in the erections, the patients at this stage complain that the organ just about gets stiff, but ejaculation takes place at once with an immediate decline of the erection, and finally, as a last stage, they can neither get erection at all nor any ejaculation. We note that there is nothing mysterious about all this, and that it is exactly what would occur in any other endorgan under similar conditions.

It must not be imagined, however, that every case goes on to the final stage. The process may be stopped at any stage by proper treatment and a discontinuance of the practice. The length of time necessary to reach each stage varies considerably in different individuals. I have seen the final stage reached after but six months of withdrawal and on the other hand, have seen patients indulge in this practice for many years, before any ill effect was noticed.

Pathology of Impotence following Masturbation.—As a matter of fact, masturbation is very infrequently an etiological factor in impotence, especially when we consider the frequency of masturbation. The man, who has never suffered from gonorrhea, and finds himself impotent, is very apt, following quack literature, to blame it on his youthful errors, errors which may have been committed ten or more years previously. I will not deny, however, that the confirmed, untreated masturbator, who marries with the idea that sexual intercourse will cure his masturbation, may find himself impotent.

The pathology in these cases is similar in many respects to that of withdrawal. There are lacking, however, the impulses from distended vesicles, for the confirmed masturbater does not give his vesicles a chance to become distended. The chief cause of the exhaustion of the erection center (R) comes from the terribly congested prostate and prostatic urethra, which has been for years bombarding the center with reflex impulses. There are in addition two other factors, which contribute toward the production of impotency in these cases. One is that the frequent manipulation of the penis has so hardened that organ that the ordinary friction of coitus (even if he is able to get his penis into the vagina) is not sufficient to arouse the more or less exhausted sexual centers. Another factor comes into play where psychic masturbation has been the predominant type. Here, also, the sexual centers have been so dulled, that it is only the most vivid pictures that the imagination can conjure up which are sufficiently strong to arouse them into action, and the ordinary acts of coitus are not sufficiently powerful to arouse either the desire or the ability for coitus.

Pathology of the Sequelæ of Gonorrhea as a Cause of Impotence.—While most German authorities lay great stress upon the sequelæ of gonorrhea as a cause of impotence, and many American writers follow their example, from my professional experience, I cannot at all subscribe to this opinion. Here again we must take into consideration that gonorrhea is such a very common disease, that in proportion to its frequency, impotence is a very infrequent complication. It might be better were it otherwise. If every man attacked with gonorrhea would become impotent, for a while at least, it would not only greatly limit the spread of the disease, but would also be a most powerful deterrent from illicit coitus.

As a sequence of severe and especially ill-treated gonorrhea, there often remains granulations, ulcerations, vegetations, and areas of congestion and erosions in the posterior urethra, especially in the region of the verumontanum. Sometimes there is also present a chronic inflammation of the prostate and seminal vesicles, which are found to be distended with purulent and other secretions. As a result of these pathological conditions, the erection center is being reflexly bombarded with impulses from these parts, and irritability and exhaustion of the center may result. The treatment of the posterior urethra, and of the prostate and seminal vesicles, generally brings about a cure.

One must be careful, however, in interpreting the results of treatment in these conditions. It often happens that the most gross pathological conditions which are seen through the posterior urethroscope are *not* the cause of the trouble, while the insignificant areas of congestion and erosions are. Very often, by removing the gross pathological lesions, we also cure by the same application or cauterization the insignificant lesions, and are thus apt to consider the cure due to the removal of the gross lesions. As a matter of fact, however, the most gross lesions may be seen through the posterior urethroscope without in any way giving any symptoms, sexual or otherwise, whereas, in other cases, a very small area of congestion in the region of the verumontanum may be the cause of the most marked nervous and sexual symptoms.

Pathology of Ungratified Sexual Excitement as a Cause of Impotence.—Ungratified sexual excitement comes into play as an etiological factor in impotence, only if it has existed for a relatively long period of time. Under this heading comes especially the temporary impotence following long engagements, in which the parties see each other very frequently and do much "spooning" and this goes on for a period of one or more years. Very often the man is continent, and often this continence is put down by some authors as a cause of impotence. As a matter of fact, the man in this case is not at all continent, in the scientific meaning of the term, he only abstains from the coital act of intercourse. We must remember that scientifically, the act of intercourse begins with the first caresses and flirtations, and that coitus is but the final stage of intercourse and not the whole thing. The man in this case really goes through all the preliminary stages of

intercourse, stopping just short of coitus. In many of these cases, the man works himself up in his passion till the point of ejaculation, but this he psychically inhibits, till the erection goes away, and then he starts in again. It is in this way the man can keep up the spooning process for hours at a time.

As a result of this practice kept up for a long time we get a chronic congestion of the posterior urethra, just like in masturbation, but in addition we have the presence of an almost continuous state of distention of the seminal vesicles, unless they are relieved by an occasional pollution. As a result of all this, exhaustion of the erection center must take place in time, in the same manner as has been described in the previous condition. This condition is represented in Fig. 3, showing the double arrows (excessive strong impulses) coming from C and V.

Finally, as etiological factors in functional impotence, we must mention a group of cases in which the pathology is obscure. To this group belong impotence from diabetes mellitus, acute febrile conditions, various forms of acute and chronic poisoning, chronic debilitating conditions, and some authors include herein such conditions as obesity and chronic nephritis.

Concerning chronic nephritis as a cause of impotence, Blum remarks as follows: "We find in many text-books impotentia coendi noted in the symptomatology of chronic nephritis. A specific inhibition of the cerebro-sexual center might be exerted by the urinary poisons retained in the blood, in analogy with other chronic intoxications. I myself, have been obliged in many cases, in which the patient complained of diminution or extinction of the sexual need, to declare chronic nephritis to be the cause. It is one of the fundamental rules of diagnosis, that we examine the urine in every case of impotence; we often come in this way, to the great and painful surprise of the patient, to an explanation of the fatal symptom."

I doubt very much whether ordinary nephritis causes impotence. As a matter of fact, I know of many men with undoubted chronic nephritis who are not in the least impotent. I have in mind at present a young man of 21, who when a child had a severe attack of diphtheria from which he almost died and which left him with a chronic nephritis, with very high arterial tension, etc., but who is very passionate sexually and not in the least impotent. Another case is that of a man of 55 with very bad kidneys, who still enjoys to the full the use of his sexual apparatus. The author quoted above cites cases where the patient complained of impotence, and where a urinary examination showed the presence of nephritis which had been unknown to the patient. He, therefore, concludes it to be the cause of his impotency. Yet time after time has it occurred to me, as well as probably to most physicians, that patients came for entirely different complaints, and a routine urine examination disclosed an unsuspected nephritis, in which there was absolutely no suggestion of impotence present. When we take into consideration that chronic nephritis is not by any means a rare disease, we must not be surprised that we find it present in a certain percentage of our impotence cases. Of course, in the last stages of nephritis with marked cachexia and uremic symptoms this condition may cause impotence just as in the case in any other debilitating disease, but I am convinced that ordinary cases of nephritis are not responsible for impotence. Blum himself seems to correct his first too general statement when he adds at page 551: "It is not surprising that in the advanced stages of nephritis with severe uremic phenomena and outspoken cachexia as well as in diabetes, sexual impotence should occur, when the exhaustion of the patient has reached a high degree." This is an entirely different state of affairs from that of an apparently healthy man coming into the office for impotence, and in which a routine urinalysis discloses nephritis. In diabetes, however, it is different. Here the disease itself seems to be the direct cause of the impotence.

Many authorities put down oxaluria as a cause of impotence. I have paid particular attention to this and have had the urine of all of my impotence cases examined, not only in the routine manner, but especially for oxalates. My experience shows, however, that oxaluria is only very infrequently found in impotence.

Symptoms of Functional Impotence.—The symptoms of impotence may be divided into local and general.

Local Symptoms.—I have previously remarked that, for normal coitus, there must be a certain sequence of events, which must proceed, in perfect harmony and proper relationship of one to the other. These events are the libido, the erection, the ejaculation and the orgasm. In impotence there may be either an absence or weakness of any one of these factors, or a disturbance in the relationship among them. We may, therefore, systematically discuss the symptoms of impotence as they effect the factors just mentioned.

1. Disturbance of the Libido.—This will be considered under psychic impotence.

2. Disturbance of Erection and Ejaculation.—Although for purposes of treatment it will be necessary to consider these two factors separately, it is more convenient at present to consider them together. The symptoms have partly been discussed in giving the pathology. It must be remembered that the patient may come to us at any stage of the disease, and that for a proper understanding of his condition, we must go into his past sexual history most minutely in order to appreciate the proper sequence of events.

In the classic type, as illustrated by the impotence of withdrawal, the patient first notices that the time consumed in coitus is not as long as it previously was. His erections are perfectly strong, he can enter the vagina, the penis remains erect for the necessary length of time, but the time between intromission and ejaculation is less. Often the penis remains erect for some time after ejaculation and may even come out in the erect condition. This must not be interpreted as an increase in the strength of erection, but as a normal erection with an abnormal or shortened period of ejaculation. The erection appears longer only in proportion to the ejaculation. Gradually, the length of ejaculation becomes shorter and shorter, at the same time as the period at which ejaculation commences after intromission also becomes markedly diminished, so that at a later stage, although the penis is erect, and enters the vagina, the ejaculation takes place immediately after intromission, or at the very moment of intromission. The patient now notices that not only is the ejaculation very rapid, but the erection itself does not last as long as usual. He will tell you that he has the desire, his penis becomes erect, but just as soon as he enters the vagina ejacu-

ation takes place at once with the decline of the penis. "The whole thing is over in a minute" is a common expression. As the disease progresses, at the very commencement of sexual excitement, the penis becomes erect, but before he can enter the vagina (often while putting on a condom) ejaculation with immediate decline of erection ensues. Finally, the penis becomes only partially erect, but goes down at once without any ejaculation at all. Later on, although libido is present, there is neither erection, ejaculation or orgasm.

It must be remembered that the patient does not of his own accord tell us the classic history as just related, but if the physician knows what symptoms to expect he will by proper interrogations get a complete history from the patient, depending upon what stage he is in. It must also be remembered that the first symptoms may come on some time after withdrawal has been stopped, and while the patient is indulging in natural coitus. He may not consider withdrawal as an etiological factor, and will not mention it, or even deny it, unless properly questioned in this regard. He may even tell you that previously, while indulging in withdrawal, his coitus was better than at present. The reason for all this is easy to understand from a consideration of the pathology. It takes some time for the centers to become exhausted, and every act of coitus, even natural coitus aids in the exhaustion process, once the pathological conditions previously mentioned are forming. So that, while he was practising withdrawal, the process had not yet reached the final stage. As long as he remains untreated, especially while irritating the parts by even natural coitus, the pathological processes will progress to complete exhaustion and impotence.

It has been customary to classify functional impotence as either paralytic on the one hand, or due to irritable weakness on the other. The general idea seems to prevail that they are separate and distinct conditions, and represent a directly opposite conditions of affairs. My experience, however, in carefully investigating the sequence of events, as well as a consideration of the pathology of impotence, has long ago convinced me that this classification is improper, and that the two conditions are but different stages of the same disease. If we carefully question patients who are suffering from so-called paralytic impotence, we will find that this condition was preceded by a stage of so-called irritable weakness. In other words, before they became totally impotent, they suffered from rapid and premature ejaculations. The pathology just gone into also explains this fully; we get first, irritation of the erection center, and finally exhaustion. It is very important to bear in mind, for purposes of treatment, that both so-called irritable weakness and paralytic impotence are one and the same.

The statement is repeatedly made, that irritable weakness should be treated by sedatives such as bromides, while paralytic impotence requires stimulants such as strychnine. Later on I will show under the heading of treatment the fallacy of this method, and prolonged clinical experience likewise proves this method of treatment to be fallacious.

There is, however, a form of rapid ejaculation which is entirely different from the form just mentioned, and which can be readily distinguished from it, if we go carefully into the sexual history. Under this heading belong those cases of healthy adults who, with no history of neurasthenia, no history of excessive masturbation or other sexual excesses, yet, after a long period of continence, have such strong sexual desire that the entire process of coitus takes but little time. They have normal libido, normal erection, normal ejaculation and normal orgasm. The whole picture represents *power* not *weakness*. It is simply an intense desire for coitus in a powerful man, who goes at it so powerfully that he is quicker than under ordinary circumstances. The condition may be likened to a swift race horse which can outrun all his competitors. The picture is entirely different from that of the man with feeble rapid ejaculation, diminished libido and lack of satisfaction from the act. In this case there is intense satisfaction from the coital act. Many men get into this condition every time they have coitus with a new acquaintance.

3. Disturbance in the Orgasm.—The exact seat of the orgasm is not known, but for various physiological reasons it is believed to be due to the queezing of the fluid through the ejaculatory ducts into the posterior urethra, through muscular action. In rapid ejaculation the orgasm is either diminished or may be entirely absent, for the following reasons: When the erection center sends its impulses too rapidly to the ejaculation centers, the impulses which are sent out by the ejaculation centers are also weaker than normal. Therefore, the squeezing out of the fluid through the ejaculatory ducts becomes less intense and the orgasm is either diminished or absent. The patient obtains no pleasure from coitus, and his partner also suffers, on account of the too short time of friction for her to get her orgasm. It is very often this lack of experiencing the orgasm that is the chief reason why the patient seeks medical advice.

Besides the symptoms mentioned above, there is an important group of cases, whose symptoms cannot be consistently classified with any of the preceding groups. Cases where there is an entire diminution of the whole process of coitus. To this class belong men, who are otherwise healthy, never suffer from neurasthenia, but in whom the sexual functions appear very late, and last only a short time. They rarely masturbate, rarely have pollutions, have very slight libido and easily remain continent. They sometimes marry for economic or other reasons, and are impotent, but do not worry very much about their condition. These men would never seek a physician were it not that they are driven there by their wives.

I cannot emphasize too strongly the necessity of recognizing the etiological basis of this condition. There is a congenital lack of sexual desire and power, which is the cause of the easy continence and the impotence in these cases. It must be recognized that these cases are *born and not made*, and that the continence is due to the same lack of sexual vigor as the impotency. I emphasize this fact, because some authorities, reasoning entirely from the previous history, but in a superficial manner, desire us to believe that the long period of continence is the cause of the impotency. I believe with Sturgis[1] and many other prominent authorities, that continence is never a cause of impotence. By continence, however, I mean not only abstinence from sexual coitus, but also abstinence from any of the factors which arouse the sexual passion (spooning, etc.). Absolute abstinence from all such factors is perhaps an impossibility, especially in large cities, which abound in erotic literature, erotic shows and moving-pictures, etc.,

but even in these cases of relative abstinence, impotence never occurs. It is only in those cases heretofore described, where, on account of long engagements, a man will fondle a girl for hours, and keep this up every night for months at a time, that *temporary* impotence might result.

Besides the local symptoms just mentioned, due to and part of the impotence itself, there is a series of local symptoms which are generally mentioned in connection with impotence, but which have really nothing to do with it. In most of the cases, the same pathological condition in the posterior urethra, the prostate and seminal vesicles, which is responsible for the impotence, is also responsible for the other symptoms. It is just as logical to consider the lancinating pains of locomotor ataxia to be due to the impotence which is also present in locomotor ataxia, as to consider the symptoms about to be described as symptoms of impotence. In both cases, both are simply due to the same underlying cause.

But, while appreciating that such symptoms are *not* symptoms of, but only symptoms often accompanying impotence, it is well that they should be mentioned here and for the following reasons: After all, we are called upon to treat the patient rather than the disease. Very often the patients complain much more about these accompanying symptoms than of the impotence. Very often also, these accompanying symptoms precede the complete exhaustion of the sexual centers for a long time, and by bearing these facts in mind, and going into the history in detail, we may sometimes arrive at a diagnosis of incipient impotence, and be able to treat the same, before the patient has really appreciated the gravity of his condition. Sometimes, too, these accompanying symptoms give us a clew to the pathological processes at work which not only cause them but which also cause the impotence.

Prominent among these symptoms may be mentioned *frequency of urination* and also *burning on urination* as well as *pain, mostly at the end of urination; vesical tenesmus, incontinence of urine*, as well as *difficulty of starting the stream of urine and dribbling* after urination are also occasionally met with. All these symptoms are due to the congested and irritated condition of the mucous membrane of the posterior urethra, as well as to the general hyperemia of all the pelvic organs which is found after a long period of withdrawal or masturbation. *Pollutions*, either nocturnal or diurnal, as well as *defecation and urination spermatorrhea* are very often accompanying symptoms of impotence.

General Symptoms.—There is a long train of symptoms, too numerous for description, which is common to all forms of impotence from whatever cause, and which may be described under the general term of sexual neurasthenia. Of this character are pains in the legs, pains over the eyes, in fact pains in any and every portion of the body. General weakness, headache, vertigo and almost any kind of or combination of symptoms is met with. As a practical point in interpreting these symptoms, care must be taken not to blame everything on the sexual neurasthenia, but to look out for possible errors in refraction, or errors in digestion, etc., as their cause.

Besides the above constitutional symptoms, there is another long list of *psychic* symptoms which has been very graphically and artistically described by German and French authors. I will not attempt to give here a graphic description of the miseries and psychic emotions of the impotent man, but will simply state that this condition is at times the cause of the most extreme unhappiness, and not infrequently leads to suicide. In fact, it has been pointed out by those who have investigated the subject that not a few of the mysterious suicides, committeed by apparently happy and contented men shortly after marriage, were due to their discovering that they were impotent.

Diagnosis.—For a proper diagnosis of functional impotence, it is necessary to take the entire sexual history of the patient into consideration. It is not sufficient to say that the patient is impotent; he knows that himself; but we must diagnose whether it is the erection center that is at fault, or the ejaculation center, the libido or a combination of all of them. It may even at times be necessary to interview or even examine the wife. This is especially important in the newly married. In one case that came under my observation, where a patient had been under treatment by several other physicians for some time for impotence, an examination of the wife by me revealed the fact that she was suffering from vaginismus, for which reason the husband could not enter, in spite of fairly strong erections. Sometimes other malformations about the female genitals prevent the penis from entering, until the poor man finally becomes discouraged and may be rendered temporarily impotent from his ineffectual efforts.

In every case of impotence we should examine for locomotor ataxia or other nervous condition which may cause it.

Prognosis.—The prognosis varies considerably in the different conditions. It is generally good in men below 45 who have been able to perform normal coitus before their present impotency. It is very poor in cases of congenital lack of sexual desire and vigor. Wherever a man has always been sexually weak from the very commencement of his sexual life, and has superimposed upon this congenital weakness the evil influences of withdrawal or excessive masturbation, the prognosis is poor. It is also not good in men past 50, or in men with a neurasthenic history to which the evils of sexual neurasthenia have been added. The prognosis is very good in those acute forms of impotence due to overindulgence in coitus, as well as in impotence from ungratified sexual passion, and in the ordinary cases of impotence from withdrawal or excessive masturbation in which there is no underlying condition of general neurasthenia. The prognosis is naturally poor in the confirmed sexual invert.

Treatment.—In order to treat properly the condition under consideration, we must have a clear conception of the pathological state of affairs and the causes which produce them. What then is the condition of affairs in the ordinary case of functional impotence? There are hyperirritated or exhausted sexual centers depending upon the stage of the disease, and a chronically inflamed posterior urethra with congested or inflamed seminal vesicles and prostate. The first indication is absolute sexual rest in order to give the exhausted centers time to recuperate and to remove every cause of irritation, which includes the treatment of the diseased posterior urethra and prostate and seminal vesicles, for as has been shown heretofore, these diseased organs are constantly bombarding the sex-

ual centers with impulses, even in the absence of sexual intercourse.

The first indication is met, by not only abstaining from coitus, but from every act which might excite the sexual passion. The husband should not sleep in the same room with his wife if possible, certainly not in the same bed. He should especially be cautioned against spooning, for if not told, some men have the impression that they can indulge in any sort of sexual play so long as they omit actual coitus. The length of time he should abstain from coitus varies in different cases. As a general rule it may be said that young and vigorous men should be kept continent for from three to six months, while men past 45 should be allowed coitus much sooner for fear of a complete dying out of the sexual passion.

Besides the abstinence from coitus, the patient should also abstain from all alcoholics, as well as from tea, coffee, eggs, and oysters, for all these stimulate the sexual apparatus and centers.

At this time nothing is so useful as the internal administration of the bromides in large doses. At least 15 grains should be given three times a day well diluted after meals. The object of this is to quiet the irritated centers, and at the same time to remove all sexual desire for the time being. This should be given even in the paralytic stage of the disease and not reserved for the cases of irritable weakness only. The large doses of the bromides should be kept up for at least two months in young persons and for one month in older patients,and then gradually reduced. It has been said that the administration of bromides may lead to impotence. Possibly the prolonged administration for years which may be necessary in epilepsy or other chronic nervous affections may have this result, but certainly for the limited time given above, no such result can occur. The patient should be fully informed of the object of the treatment or else he is apt to be discouraged and tell you that his condition is getting worse instead of better. He will inform you that before he started treatment he had some sexual desire, while now he has none. As a matter of fact, this is just what is wanted and is the main object of the administration of the bromides. The patient should therefore be informed of these facts at the very start.

At the very commencement of treatment, in fact at the first examination, we should inform ourselves of the condition of the prostate, seminal vesicles, and urethra, especially the posterior urethra. For this purpose a routine genito-urinary examination should be made, including a search for stricture and an endoscopic examination of the entire urethra. A routine urine examination should be also made to rule out diabetes as a possible etiological factor. In many of these cases we will find areas of congestion or other pathological conditions in the region of the verumontanum. The prostate and seminal vesicles will also often be found enlarged and sensitive.

For the treatment of these pathological conditions in the posterior urethra nothing succeeds so well as the instillations of weak silver nitrate solutions through the Bangs sound syringe, just as in cases of masturbation. The instillations are given every five days, starting with a 1 3000 solution and increasing to ½ per cent. The size of the sound is also increased till the largest possible can be taken. Should there occur at any time too much irritation from the instillations, as evidenced by urethral discharge or very intense burning, the strength of the silver solution should be reduced. Of course, if the endoscope reveals any gross pathological condition in the posterior urethra, such as cysts, vegetations, or similar conditions, these should be removed either by puncturing or other intraurethral operation, which is very feasible through the modern posterior urethroscope. After the very acute condition of congestion has been removed by the above instillations, a few direct applications of very strong silver solution (10 to 20 per cent.) can be made advantageously to the diseased areas through the urethroscope.

I have often been asked how the application of silver nitrate to the verumontanum could possibly cure impotence. To this I must answer that the application of silver nitrate to the *normal* verumontanum can only do harm, but he who has looked through the modern endoscope and has seen the pathological conditions present can readily understand how the removal of these conditions can have a beneficial effect upon the coital act. I desire especially to emphasize the fact that the treatment is not psychic, although the introduction of the lighted endoscope cannot help having a psychic effect on the patient. The treatment and the good results of the treatment are due solely to the removal of the pathological conditions present. The indiscriminate application of strong caustics to the verumontanum, practised years ago as a cure for impotence, has deserved the severe censure which it has received, but the rational treatment of the diseased areas which can be so distinctly seen through modern instruments, is of distinct benefit to the patient.

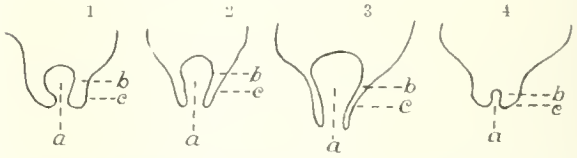

FIG. 2.—Diagrammatic pictures of the normal and diseased verumontanum. 1, Normal; 2, moderately enlarged; 3, greatly enlarged; 4, atrophic; *a*, verumontanum; *b*, lateral sulcus; *c*, urethral wall.

One must have considerable experience in posterior endoscopy, however, before he can recognize what is pathological and what is normal. The verumontanum, like the trigone of the bladder, is *normally* redder than the surrounding parts, and the inexperienced observer is likely to consider the normal verumontanum to be congested or inflamed. The same holds good also concerning its size. We must remember that the normal verumontanum varies greatly in size and shape in different individuals. In the colored race, for instance, where all sexual organs are markedly developed, I have noticed that the verumontanum is much larger than in white persons. I have evolved the following rule as a guide: we must not go by the absolute size of the verumontanum but by its size in relation to the posterior urethra in which it is found. In other words, a verumontanum, which almost completely fills the prostatic urethra, showing little if any signs of lateral sinuses, that is to say, if it almost touches the walls of the urethra on either side, is to be considered considerably enlarged. One can easily appreciate how such a verumontanum must keep on tickling the walls of the prostatic urethra even in the absence of coitus, and also how irritating it must be when rendered more congested during the coital act.

It must be remembered that the posterior endoscope only shows the pathological condition of the posterior urethra, and that similar pathological conditions are found in other conditions such as masturbation, satyriasis, etc. In other words, *one cannot make a diagnosis of impotence by merely looking through the endoscope.*

At the same time that we are treating the pathological conditions in the posterior urethra, we also treat the enlarged, congested and sensitive prostate, and seminal vesicles, by *gentle* massage every five days. *Gentle* massage is an art, which it requires much practice to obtain. It is a pity that any manipulation of the prostate is designated by the term massage. This is really a mistake. When we manipulate the prostate in cases of gonorrhea in order to get out its secretions for diagnostic or therapeutic purposes, we are justified in using quite hard pressure, but this process ought really be called expression instead of massage. Such procedure is entirely different from what the one now under consideration should be. It must be remembered that the object of the manipulation is not to squeeze out every drop of secretion from the prostate, but to relieve the congestion, and to help the exhausted muscles of the prostate to regain their tone. In other words, massage in the same sense in which that term is used when applied to other portions of the body. Using powerful pressure on the inflamed and sensitive prostate is no more massage of that organ than punching a man in the belly would be considered massage of the abdomen.

This combined treatment, to wit, agstinence, restricted diet, bromides, intraurethral treatment, and prostatic massage should be kept up for several months depending upon the age of the patient, the stage of the disease, and also the reaction to the treatment. During this time, his general health should receive the closest attention. A liberal and easily digested diet, largely made up of cream and other fats should be ordered. Constipation must be relieved, as it tends towards interference with the return pelvic circulation and thus makes for local congestion. Tonics and out-door exercises should be ordered where feasible. A very useful adjuvant is cold baths, or cold spinal douches. These are to be taken only in the morning and never at night. Hot baths are positively injurious.

If at any time frequent pollutions occur, we must at once suspend massage of the prostate, otherwise this procedure is to be kept up at increasing intervals, until that organ is no more congested and its sensitiveness is gone. One must have some experience, however, in deciding these points, as we can always squeeze hard enough even on a normal prostate to cause pain.

When we have decided that the sexual centers have fully recuperated, and observe that the posterior urethra, as well as the adnexa, are normal, we stop the bromides and turn to sexual stimulants. I have tried most of the drugs recommended, but have gradually narrowed down my medical armamentarium to two drugs, namely strychnine and yohimbin. Strychnine nitrate is to be preferred, although where this is not obtainable, the sulphate acts almost as well. I have become convinced that those who have not obtained good results from this drug have not administered it in the proper way or dosage. Many years ago, that great clinical observer, Abraham Jacobi, stated that the dose of this drug for children is generally put down as much too small, and I have come to the same conclusion in regard to its use in adults. Where coitus is indulged in during the night, I order 1/20 grain of either strychnine nitrate or sulphate to be taken at 5 P. M., 7 P. M., 9 P. M. and 11 P. M. Although the patient thus gets gr. 1.5 in six hours I have never noticed any bad effects from it. At first there may be some headache, but this soon passes off, and the patients frequently tell me that they sleep much better than before. It should be stated here, that strychnine has no direct effect upon the sexual desire. All it does is to make the penis stiff so that it can enter the vagina, and remain in the erect condition during coitus. Frequently the penis even remains stiff after coitus is completed, and comes out in an erect condition also. Yohimbin acts very well within certain limitations. It must not be given as long as precipitate ejaculations are present, or where frequent pollutions complicate the impotence. It is not to be given continuously, but should be given for from one week to two weeks at the utmost, in doses of one tablet three times a day. Its chief application is after a long period of sexual continence, and when the erection center has been completely rested. The rested center will now react splendidly to this drug and the first and much feared coitus will be successful. Some authors recommend it to be given subcutaneously. Lissman[5] reported excellent results with the epidural injection of yohimbin solution, even in cases where the tablets had failed. I have had no experience, however, with either the subcutaneous or epidural method of administering yohimbin. But given in tablet form at the right time and within the limitations above mentioned, it has generally worked very well.

I desire to record here some experiments I have made with tincture of cantharides in cases of impotence. It is well known that this drug, if taken in large enough doses, may cause priapism, for which reason it had often been given for the purpose of bringing on erection. The drug is, however, a very powerful irritant to all mucous membranes. If taken internally, in sufficiently large doses, it causes a gastroenteritis, a nephritis and an intense inflammation of the mucous membrane of the bladder and urethra. It is by causing this inflammation of the genitourinary mucous membrane that the erections are brought on, and death has at times resulted from its use for this purpose.

Several years ago, it occurred to me, that if cantharides has this effect, what is the necessity of administering it in poisonous doses, thereby causing gastroenteritis, nephritis and cysitis in order to bring a sufficient quantity of the drug into contact with the mucous membrane of the urethra in order to cause erection, when by means of the endoscope or with the syringe the drug may be applied directly to the urethral mucous membrane? Accordingly, I started my experiments with very weak solutions, and gradually increased the strength until it became evident that about 50 per cent. or at most a 75 per cent solution of the tincture of cantharides was as strong a dosage as could be given by instillation. I even made direct application of the pure tincture of cantharides to the verumontanum, and, while irritation was produced, as shown by burning and frequency of urination, there was never the slightest indication of erection. No harm resulted to the patients from these experiments. Cantharides given internally may possibly be excreted with the urine in some peculiar chemical combination, or may form some chemical combination in the

blood, which is excreted in such a form as to irritate the erection center and thus cause the priapism. A search through medical literature for some explanation as to how cantharides is excreted threw no light upon the subject. To those who have access to physiological laboratories it might be interesting to work out this problem, or the experiment may be tried by giving rabbits or other animals poisonous doses of cantharides, and then collecting their urine to ascertain what effect this urine may have if applied directly to the posterior urethra.

The treatment of those cases in which there is a congenital lack of sexual vigor is very unsatisfactory, and all we can do is to conserve whatever power they have by warning them against excessive coitus and withdrawal.

It is very important to impress upon patients that the best we can do is to get their organs into normal condition, but that we cannot so educate their organs that they can abuse them without coming to grief. In other words, if we have succeeded in curing the impotence which was caused by coitus interruptus, the patient must be made to understand that if he resumes the practice he will surely relapse, and the same is true of the other eitological factors.

III. Psychic Impotence.

Definition.—Psychic impotence is that condition in which the impotence is caused by inhibitory influences from the higher centers. While in organic impotence the trouble is with the endorgans, and in functional impotence it is generally the sexual centers which are at fault, in psychic impotence there are healthy endorgans and healthy centers, but the actions of the centers are interfered with by inhibitory influences. Groag justly calls attention to the fact that the term has been very unhappily chosen, inasmuch as some of the other forms of impotence are also partially psychic and he, therefore, suggests the term Inhibition Impotence instead.

Etiology.—Any act of factor which can influence the imagination may be the cause of the inhibition. Among the more common factors may be mentioned fear of venereal disease, fear of pregnancy, fear of being caught in the act, fright, disgust of the partner, fear of being impotent on account of youthful masturbation, etc. Among the unusual causes may be mentioned joy, as in a case reported by Roubaud where a man became impotent on hearing that he won a large sum of money in the lottery; marital indifference, as in a case mentioned by Sturgis,[1] in which the wife considered the conjugal act to be vulgar and indecent, and during coitus indulged in running comments upon the performance; superstition is reported in a case by Hammond, where a man believed his wife had given him a certain glance to make him impotent while away from home; the celebrated case mentioned by de Caux, in which a mathematician was always diverted from coitus by a certain geometric problem coming up at the psychic moment.

Pathology.—In ordinary coitus, as soon as the libido is aroused an impulse is sent from the cerebrum (*C* Fig. 1, page 12) to the erection center (*R*) and erection occurs. In the condition under consideration the libido is normal, and even may be very powerful, but inhibitory impulses are sent from other cerebral centers to *C* preventing it from sending impulses to the erection center (*R*). In those cases where erection has already commenced, the inhibition is transmitted further from *C* to *R*, thus stopping the forming erection.

Symptoms.—There are two forms of psychic impotence: (1) Misdirected libido, (2) inhibited libido.

1. Misdirected libido.—(*a*) Sexual perverts. Normally, the libido of a mature man is directed towards a female. If, however, the libido is directed toward any other source, the person is a pervert. Sometimes such men marry for social or economic reasons, but the presence of the wife does not excite in them the libido, and they are impotent. The seat of the trouble is probably in the cerebrum (*C*).

(*b*) Impotence of the roué. On account of too frequent coitus these persons find no longer pleasure in normal coitus, and therefore seek for stronger and stronger methods of excitement in order to cause erection (Mol's excitement hunger). According to our diagrammatic scheme, the impulses from *C* (cerebrum) to *R* (erection center) are too weak during normal coitus to excite *R*, so that a strengthening of the impulses, through the addition of new psychic excitements, is necessary.

(*c*) Relative Impotence. Under this heading may be mentioned those cases where the husband, after many years of married life, becomes impotent with his wife, though perfectly potent with other women. To this class also belong those curious cases, where men are potent only with certain types of women, either blondes or brunettes or other physical characteristics, and are impotent with all other types of women. Also those cases in which the man can only indulge in coitus if the woman has a certain kind of dress on, or her hair done up in a certain way. Groag[1] rightly remarks that the term has been very unhappily chosen, as the two previous kinds of impotence just described are also cases of relative impotence.

The three forms of impotence due to misdirected libido just mentioned are sometimes classed under functional rather than psychic impotence.

2. Inhibited Libido.—The symptoms have already been partly described with the etiology. The person has normal or even intense libido, but just at the exciting moment either the erection fails to occur, or if it has started it suddenly ceases. At each further attempt the same thing occurs, and may even be worse. The same train of neurasthenic symptoms may follow this condition, as has been mentioned in the other forms of impotence. As far as the patient is concerned he is just as unhappy as if the impotence were caused by the most pronounced organic or central lesion.

Diagnosis.—The diagnosis can only be made by a careful consideration of the patient's history together with a most careful genito-urinary examination, as well as a general examination. Cases which at first blush seem to be obvious cases of psychic impotence may on careful examination turn out to have a definite organic or functional etiology. The most important points in the diagnosis are the presence of normal libido, the absence of organic defects or diseases, the absence of a history of coitus interruptus or other unnatural sexual excitation, and the presence of a definite psychic history.

The *prognosis* is generally excellent.

Treatment.—The treatment is entirely psychic, but this does not mean that the patient should be neglected. It is a grave mistake to tell the patient there is nothing the matter with him, or even to

laugh at him. For this reason as well as for proper diagnosis it is well to carefully examine him, because the thoroughness of the examination impresses the patient and helps toward the cure. Endoscopic examination in which the patient sees the lighted instrument enter the canal and appreciates that the physician can see everything inside is especially impressive. Electricity has here its greatest value. It is this form of impotence that has been cured by anything varying from a bread pill to Christian Science. Hammond has been successful by giving the patient some indifferent pills, telling the patient that he may sleep with his wife, but under no circumstances indulge in coitus until all the pills have been taken. Very often the patient breaks the rule and finds himself potent. It may be necessary to instruct the wife and have her assist in the coital act, and by her common sense in many ways also. In the case of the mathematician above referred to his wife cured him by making him partially intoxicated before coitus. A change of scene or even different lodgings has resulted in a cure.

IMMUNIZED MILK IN THE PROPHYLAXIS AND TREATMENT OF TYPHOID FEVER.

By JULIUS ROSENBERG, M.D.,
NEW YORK.

About two years ago I published (*N. Y. Med. Journal*, Oct. 11, 1913) a brief preliminary report of my observations, that cows and goats immunized with dead cultures of the typhoid bacillus, according to the methods of Pfeifer, Kolle and Wright, developed in their milk specific antibodies, agglutinins and precipitins, that feeding this milk to animals or human beings would convey passive immunity and protection against the typhoid bacillus, and that I obtained positive evidence that ingestion of this milk would cause the production of specific antibodies in the circulation, so that the blood, at first negative, would subsequently respond to the agglutination test. These observations justified, in my opinion, the assumption "that immunized milk would provide protection against typhoid infection, a prophylactic like anti-typhoid vaccination, without its risk and the usual symptoms of discomfort." I mentioned that immunized milk seemed to be a rational remedy for treating typhoid fever, especially in the earliest stages, deserving preference to ordinary milk.

I was working in a sparsely settled country district, about 150 miles distant from New York City, with limited facilities. In the closing sentences of my report I asked for the co-operation of hospitals and physicians, *offering to deliver*, daily, the needed quantity of immunized milk, free of expense, to all desirous of testing the merit and practical value of immunized milk. I furnished to a number of applicants about twenty quarts of immunized milk a day for a period of from one to three months, but the results were a great disappointment, a waste of time and money.

Some accepted the gratuitous supply for many weeks, but never reported their observations. It is very doubtful if ever any tests were made, and I could not obtain a satisfactory answer to my queries. Others furnished careless and incomplete reports, lacking essential details, utterly useless, only fit for the waste basket. Not one of the reports supplied dependable data; all were valueless. I mention this probably not singular experience to illustrate the difficulties, the obstacles, encountered in attempting to present a subject fairly and truthfully.

The criticism of probable lack of judgment and care in the selection of associates is answered by the fact that both individuals and institutions have a good reputation. Dr. Benjamin Corwin conducted a series of tests at the Kings County Hospital, Brooklyn, which had to be discontinued before satisfactory results were obtainable, owing to the variable condition of the milk supply. The investigation is about to be resumed with immunized milk from cows kept in the vicinity of the hospital.

Knowing my observations to be true and well founded, I made many efforts to induce other competent and conscientious workers to test the effect of immunization upon milk, and the transmission of antibodies into the alimentary canal, but my attempt to win support for my proposition encountered undivided skepticism. All were imbued with a firmly rooted conviction that the intestinal wall constituted a solid barrier to the passage of antibodies, that none would pass the intestinal mucous membrane, except that of very young animals, the latest possible period being the second week of extrauterine life.

However, in the end, time, persistence and truth are bound to succeed. To-day I am able to state that the essentials of my first preliminary report are verified by other observers by evidence which must be accepted beyond a question of doubt.

Yoshinaga of the University of Tokio (*Z. f. Bacteriology*, Bd. V) inoculated goats and reports the subsequent appearance of agglutinins, precipitins and opsonins in the milk; that the milk responded to the Gruenbaum-Widal test; that it contained well-marked bactericidal properties; that feeding this milk afforded protection and resistance against the typhoid bacillus; that the blood contained the specific antibodies.

Dr. W. H. Park, director of the New York City Board of Health Research Laboratories, tested the effect of immunization upon cows and calves five to six months old. His reports are as yet unpublished. I am, however, permitted to state that the milk, as a result of immunization, responded to the agglutination tests; that the feeding of this milk to practically adult animals caused the presence of antibodies in the circulation, the transmission of passive immunity, the passing into the blood of antibodies by way of the intestinal canal.

These tests proved the correctness of my observations, that inoculation of the parent animals caused the appearance of specific antibodies in the animals' milk, that feeding this milk to mature animals provided the subsequent evidence of antibodies in the circulation; a complete chain, a perfect circle of proof.

The effect of immunization upon milk, the transmission of antibodies by way of the intestinal canal must be accepted as proven. Any failures to con-

firm this are due to errors in technique, incomplete immunization, deterioration of the milk, etc.

What is the practical value of immunized milk? This is a pertinent question. The value of anti-typhoid vaccination is undeniable. There is abundant evidence that anti-typhoid vaccination causes a reduction of the morbidity, also the mortality of those who become infected in spite of inoculation, but it is quite probable that similar results will follow the use of immunized milk.

Immunized milk is absolutely safe and harmless, while anti-typhoid vaccination often causes more or less severe systemic symptoms. In about one-third of all cases anti-typhoid vaccination is followed by a rise of temperature, a general malaise lasting two to three days. Ten per cent of the vaccinated patients become quite ill, are forced to keep their beds, and for almost a week are utterly incapacitated for work.

These observations, of which the literature contains several reports, pertain to young men in exceptionally excellent physical condition, mostly soldiers in active service. It is more than probable that the universal use of anti-typhoid vaccine would not be void of danger to health, if not to life. We know even now that many individuals, those most in need of protection, must be excluded from anti-typhoid vaccination because it is dangerous and contraindicated on account of physical defects; to these immunized milk offers a safe and simple method of protection.

Immunized milk is an excellent medium to provide general immunization for typhoid fever at trifling expense and without risk. It causes neither local nor systemic ill effects. It is fatal to but one organism, viz., the typhoid bacillus. Drinking one quart of immunized milk per day for a period of about two weeks provides adequate protection for two months. Immunity, however, can be prolonged indefinitely by drinking one or two quarts of immunized milk every ten days to two weeks.

The data are, of course, not final, and to obtain precision much additional experience is required. It should, however, not be overlook that facts regarding anti-typhoid vaccination are by no means definitely established. Estimates of the time limit of protection vary from two months to two years; the majority accept one year as a fair average.

Wade and McDaniel (*Am. Journal of Public Health*, February, 1915) report 177 cases vaccinated with anti-typhoid vaccine, and found that the Widal reaction following vaccination is of short duration. In but a very small percentage the reaction persists after six months (in 16.3 per cent), and by the end of one year the evidence of agglutinins in the body is reduced to 11.7 per cent. According to Moon (*Journal for Infectious Diseases*, December, 1914), the absence of the Widal reaction not necessarily indicates an absence of protection. Moon believes that the immunization effect of anti-typhoid vaccine lasts for about two years, but beyond that time should not be relied upon. The only proof in our possession is the fact that typhoid fever still claims a large annual sacrifice of lives.

Louis J. Dublin, Ph.D., statistician of the Metropolitan Life Insurance Company, estimates the number of deaths in the United States from typhoid fever to be not less than 20,000 per annum, to which must be added another 8,000 deaths due to sequel. The yearly average of sickness is 198,000 cases (*Am. Journal of Public Health*, January, 1915). Besides an efficient prophylactic, immunized milk will probably prove itself to be a valuable aid in the treatment of typhoid fever, especially in the early stage of the disease. Immunized milk should be used at the very onset, even before a diagnosis is possible, and should be given in every suspicious case; it may succeed in aborting the disease, preventing the infection by augmenting the body's natural defenses. It will provide the needed antibodies to destroy the invading host, neutralize the bacterial toxins at a period when the body is not as yet prepared to cope with the infectious organism. The use of immunized milk in the treatment of typhoid fever rests upon sound scientific principles; it deserves a careful and extended practical test.

Why not use immunized milk in preference to ordinary milk? It contains the specific antidote for the typhoid bacillus, which by feeding the milk is conveyed into the intestinal canal in direct contact with the invading host.

There is every reason in favor of immunized milk, and no possible argument against it. Patients ought to be afforded the opportunity to obtain its advantages, to profit by its assistance in the combat against the disease. The production and distribution of a dependable immunized milk requires the facilities of a well-organized dairy. I have arranged with a responsible concern to provide and deliver a high-grade immunized milk at a reasonable price. I will personally supervise the immunization of the cows, and to guard against errors, each bottle will bear a special label as suggested and permitted by the Department of Health. I hope that in course of time dairies in other cities will arrange to supply immunized milk.

57 East Seventy-seventh Street.

SECTION OF THE POSTERIOR ROOTS OF THE SIXTH TO TENTH THORACIC NERVES FOR THE RELIEF OF SEVERE GASTRIC CRISES IN LOCOMOTOR ATAXIA.

By FREDERIC W. BANCROFT, M.D.,

NEW YORK.

The following is the report of a case admitted to hospital September 20, 1911:

C. F., aged 33, U. S. printer (working with Babbitt metal and lead). He has complained for two years of stomach trouble with attacks of vertigo and weakness in the legs.

Family History.—Father living, aged 56, good health. Mother died at 51, paralytic stroke. Brothers, five died in infancy; one at 11, of an infantile disease. Sister, one during childbirth, three died in infancy, cause unknown. Has two maternal uncles who are chronic alcoholics, both advanced in years, and enjoy excellent health. Wife died at 23, through accident; has one child living, in good health, age 5.

Personal History.—Born in New York City 33 years ago; at school until 13, selling papers on the street for three years. Been on the New York *Sun* since, as sterotyper, working always with hot metals, largely composed of lead. Alcohol, none except two or three beers a week. Tobacco, smokes and chews freely. Appetite, good. Bowels, regular. Weight, 125 pounds. The patient had an operation at St. Gregory's Hospital, nineteen months ago; he says "They removed 8 inches from stomach, it being too large"; good recovery after one month. At 14 he had gonorrhea with chancre (hard) and two buboes. Was treated with santal and injections for six months.

Present Illness.—Cramps in stomach, February 19, 1909, with vomiting of a greenish, slimy liquid as well as undigested food; no blood, but sharp shooting pains, causing localized distention, with sensation of tumor masses; during twenty-four hours the vomiting was projectile in type, the attacks coming with no relation to time of eating. He was very weak after these at-

tacks, headaches most severe, radiating from the back of the head around forehead; complete loss of appetite, and on trying to walk, all objects would turn black. Then he would go to bed for two or three days, eating nothing, getting little or no sleep. Attacks irregular, two or three months apart, increasing. Loss of control of bowels and bladder has increased, but he has never lost entire control. Memory and eyesight, as well as hearing good. Sexual power diminished six months ago.

At the start the diagnosis was lead colic; treatment gave temporary relief, but there was a recurrence four months later. Six months later he entered St. Gregory's Hospital, and was operated on, as before stated, the diagnosis being dilated stomach. No relief followed, irregular attacks occurring as before. Salvarsan was given on February 11, after a diagnosis of tabes dorsalis had been determined on; he gained 8 pounds in weight after this, and pains were diminished. On March 11 his wife died, and the shock of this caused an attack that lasted twenty-four hours, and thereafter the attacks became so frequent and left him so weak, that he had to quit work entirely. He was at the Neurological Institute in May, 1911. The Wassermann was made and was positive. The patient was given mercury subcutaneously, but no improvement followed. He remained at the Institute one week, and continued the mercurial treatment until September. At Bellevue the Wassermann was negative, then an *x*-ray examination was made but it disclosed nothing. During the past eight months he has noticed a stagger in his gait and increasing diplopia; has had shooting pains in legs and back for past five years, relief from which is obtained by hot baths.

General appearance, of medium frame, fairly well developed and nourished, skin and mucous membranes of fair color. Attitude, stands and sits in a slightly stooping position: gait, nothing characteristic; weight, 103.

Mental Status.—Attention easily obtained and retained; memory good. Orientation time and place, normal. Intelligence, fair. Association of ideas, past and present is good. Speech is rather slow pitched, no scanning or tremor. Sleeps poorly.

Reflexes.—Cutaneous, abdominal; UM and L, all present; cremasteric, absent; interscapular, gluteal, and anal, present; no plantar response; patellar and Achilles, absent; elbow and wrist, normal; no clonius or Oppenheimer-Gordon syndrome; bulbucavernous absent.

Pain sense diminished in muscles, testicles, and eyeballs; general tolerance to pain. Faint, indistinct band of hyperesthesia to pin and cotton wool is present between third and seventh ribs to the anterior axillary line. Thermal and localization seems good. Touch less than 5 c.c. apart, two points not differentiated. Pressure and pain almost absent.

Complicated sensory functions.—Postural is markedly diminished, in upper and lower extremities, active and passive movements fairly distinct; ataxia is marked in lower, slight in upper extremities. Stereognosis good.

Musculature is flabby, resistance good. Incoordination of upper extremities slight, of lower more marked. Romberg present. No fibrillations, twitchings, flaccidity, or mechanical restrictions. Control of bladder and rectum is slight, frequency of voidings is increased. Trophic disturbances of skin or bone are absent. Vasomotor response normal.

Cranial Nerves.—1st, 5th, 11th, and 12th normal; 3rd, 4th, and 6th, eye movements, good in all directions; slight lateral and vertical nystagmus, on extreme movement; no von Graafe, pupils dilate 4 mm. in diameter, equal, normal position, do not react to light, or in accommodation.

Chest.—Marked supraclavicular depression, slight infraclavicular expansion; slight increase of tactile fremitus in the right upper side, and slight dullness, whispered voice markedly increased in right Apical region. Heart normal in size, shape, and position; sounds good, no accentuations. Pulse, 90; volume small, force poor, and not well sustained.

Wassermann Reaction.—German Hospital, February 11, positive; Neurological Institute, May 11, positive; Bellevue Hospital, September, 11, negative.

Diagnosis.—Tabes.

Upon admission to the surgical ward of the Central Hospital, the patient was having intense attacks of gastric crisis, which would last from two to four days. During this time he had to be under the influence of morphine, which, even then, did not relieve the intense pain in the epigastrium. During these attacks, the skin over the lower thoax and epigastrium was markedly hyperesthetic; he would vomit everything, including water, for 36 to 48 hours, the amount of fluid lost was often very great.

Operation was performed in February, 1914, in the Central Neurological Hospital, on Blackwell's Island, under gas and ether anesthesia.

A laminectomy of the 6th, 7th, 8th, and part of the 5th thoracic vertebræ, was performed. The dura was exposed and opened. As in this region the posterior roots come off about three vertebræ above their point of exit, it was possible to section the 6th to 10th roots. The posterior roots are larger than the anterior, and there is a slight technical difficulty in identifying them, as they lie close together, before leaving the dura. After excision of about 1 to 1.5 cm. of the roots, the dura was sutured with fine "O" catgut and the muscles sutured over the posterior part of the vertebæ. The skin was closed with interrupted sutures of silkworm-gut.

In regard to the technique of the operation, I should advise an osteoplastic flap, in preference to a laminotomy, but this was impossible, with the instruments available. Sections of the dorsal roots were taken for microscopical examination.

The patient had an acute dilation of the stomach for three days, but after that, he made an uneventful recovery. He complained of very little pain and did not vomit after the first three days while in the surgical ward. He was later transferred back to the neurological ward, where he is at the present time. Since that time, however, he has had no attacks of gastric crisis; he has had some moderate pain in lower abdomen, but no crisis. He vomits about once a day, usually in the morning, but during the rest of the time, is able to eat about what he wishes. His general condition is about the same as before the operation. There is a linear scar over his back. He is able to bend his back and move it without difficulty. On palpation, there is a groove in the place of the excised spinous processes. There is a definite area of anesthesia in the distribution of the excised spinal nerve roots. His condition is improved but he is not cured.

The sections taken for microscopical examination, were stained by hematoxylin, eosin, Cajal method and the Marchi. Dr. Tilney, of Columbia University, very kindly made the following report of the sections: "Some of the finer fibers in the root appear degenerated. The axis cylinders are fragmented and in addition to this there is a distinct increase of the comitus element of the perineurium. This latter character is the most prominent departure from the normal condition. The Cajal preparations may be interpreted in the same way, the coarser neurofibrils appearing perfectly continuous throughout the section, while there are numerous finer fibrils of a fragmented variety. In this interpretation, the reservation must be made that silver impregnations are prone to be incomplete, and consequently the fragmented condition of the finer neurofibrils may be the result of imperfect impregnation."

In gastric crisis there is intense nausea with severe pain in the upper abdomen, worse in the epigastrium and under the costal margins. This is usually accompanied by a hyperesthesia of the skin over the lower thorax and upper abdomen.

The epigastric reflexes are markedly exaggerated. The vomiting may be almost constant. Forster reports a case who vomited 8 liters of fluid during 24 hours and another who lost 6 pounds in 24 hours. In a few cases blood is vomited; this is usually due, however, to diapedesis rather than to any gross lesion. There may be severe salivation and increase of the bronchial secretions. The urine is usually decreased. There is often a rise in temperature. Between attacks there may be complete cessation of pain and vomiting. The attacks may follow so rapidly upon one another that a condition named by the Germans "status kriticus" may develop, with constant pain, nausea, and vomiting, followed by rapid inanition.

According to Newman, L. R. Muller, and Head the course of the sensory fibers of the stomach is through the celiac axis, through the great splanchnic nerve and the rami communicantes to

the dorsal roots of the sixth to ninth thoracic nerves. The dorsal roots take also the sensory fibers from the epigastrium. The sympathetic fibers of the gall-bladder pass through the seventh to tenth posterior roots, and those of the intestines through the ninth to twelfth posterior roots. Siding has reported a case of severe gastric crisis, with a herpetiform eruption over the areas supplied by the sixth to ninth nerves. Roux has found that the fine nerve fibers which connect the dorsal roots to the cells in the sympathetic ganglion are particularly degenerated in tabetic subjects; while the strong medullary fibers, originating in the intervertebral ganglion, are not diseased to any appreciable extent.

On the other hand, other authors state that there are sensory fibers from the stomach passing through the vagus nerve. Eppinger and Hess have concluded that gastric crisis is explained by irritation and later paralysis of the autonomous system (vagus nerve); their work has been carried on experimentally. Forster claims that, if it were due to vagus irritation there would be no skin hyperesthesia, and laryngeal crisis and heart symptoms would be present. He thinks there is one type of gastric crisis associated with laryngeal crisis and vomiting without gastric pain, that may be due to vagus irritation or to direct injury to the vomiting centers in the medulla.

Abbe and Bennett, in 1888, first conceived the idea of section of the posterior roots for pain. Their case was one of neuralgia of the brachial plexus. Later, Giordano operated on a case for the relief of sciatica.

In 1900 Mingazini proposed the intradural resection of the posterior sacrolumbar roots in a case of tabes with severe lightning pains in the legs.

In 1906 Atlas and Cotte, in a case of severe gastric crisis with vomiting, opened the abdomen, dissected the solar plexus free from the celiac axis and stretched it. The attacks of crisis stopped immediately.

Forster, in 1908, advised sectioning the posterior nerve roots in severe cases. He considered that the irritation of the dorsal root fibers manifests itself in the severe pain and vomiting, in the tremendously increased hyperesthesia of the skin, of the epi-, meso-, and hypogastrium, and in the exaggeration of the epigastric reflex. As a rule, the pain and hyperesthesia appear first, while the motor disorders, as vomiting, occur later.

Forster performed the first rhizotomy for gastric crisis, resecting the sixth to tenth posterior roots. There was no return of crisis before the patient's death, nine months later, from tuberculosis. Guleke has performed the operation. He, however, does not open the dura, but divides the nerves after they leave the dural sac. Franke, in March, 1910, advised severance of the posterior roots by avulsion of the intercostal nerves, without opening the vertebral canal. He reported a case with complete recovery.

In an excellent article in the *American Journal of the Medical Sciences* in 1913, Fraser reports a case with a thorough review of the literature. I have quoted liberally from his text. At that time 30 cases had been reported. Of these 9, or 30 per cent., were completely cured, 16, or 56 per cent., much improved. Several of the reported cases have been very gratifying in their results, the patients having gained weight, and their general condition having improved; in one case reported by Kuttner, the patient gained over 40 pounds.

The author's case has shown a very definite improvement, as the intense crisis has disappeared entirely. While one year is not a sufficient length of time to determine the permanent result of the operation, it shows that there is a certain definite demand for the operation when all medical therapy has been exhausted. With the improved treatment of tabes dorsalis, with salvarsanized serum injected intraspinally, the demand for such a procedure must, however, be very limited.

In the type of case that resists all therapy and where the suffering is intolerable, it offers relief from an otherwise hopeless condition.

8 East Fifty-fourth Street.

THE INTELLIGENT TREATMENT OF DISEASES OF THE SKIN.

By WILLIAM S. WALSH, M.D.,

PROVIDENCE, R. I.

While it is true that our knowledge of dermatology is at the best very meager, there is no reason whatsoever why the general practitioner, especially, should throw down his hands in hopeless despair when he is called upon to treat an apparently incurable dermatic trouble. And though it is the wont of the average practitioner to confess his ignorance of diseases of the skin, still if he were to study his cases of this nature as thoroughly and painstakingly as he does those diseases more applicable to the realm of internal medicine, he would very often find that the dermatoses which he previously regarded as incurable, if not capable of being totally eradicated, were, at least, susceptible of improvement. But, sad to state, the busy doctor, conscious of the fact that his more erudite brethren, the specialists, are still forced to acknowledge their frequent therapeutic defeats, and underrating his own ability, is wont simply to prescribe one or more of the various ointments or lotions applicable in any skin lesion and to dismiss his patient with the unscientific and often erroneous statement that the disease will disappear of itself.

In every disease of the skin, save probably those whose etiology and specific treatment are definitely known (and they are few indeed), a thorough physical examination of the patient is indispensable if intelligent treatment is to be instituted. If we were to regard the lesions of the skin as merely a symptom rather than a disease, greater progress would be made, but, unfortunately, the majority of us still believe in the old adage to the effect that there's a salve for every sore. There may be specific ones to be sure, but the number of such can be counted on the finger ends, and very often the local application which cures one disease in one patient aggravates the same condition in another.

Not only is a physical examination necessary, but a chemical examination of the body secretions, and excretions as well, for even though the pathological conditions that may be found may not prove to be a direct causative factor of the disease, it is proper to assume that the disturbed metabolism indicated by the abnormal findings tends to aggravate the diseased condition of the skin, and so renders local treatment unsuccessful. It is true that the same pathological conditions, such as we may find in

some patients, may be present in others who betray no sign whatsoever of a diseased skin. But we must remember that all persons do not react similarly to the same irritant or disturbed function. All persons exposed to diphtheria do not take the disease, and by the Schick test we find that these persons have antitoxin enough in their blood to ward off infection. So also is the case in many other of the diseases we encounter in general practice, and for lack of better knowledge we say they possess an immunity. And if the term immunity is applicable and seems to explain the insusceptibility of certain people to such general diseases, it is also applicable to the field of dermatology. For instance, why are some men able to handle *Rhus venenata* and develop no dermatitis while others are severely affected? Why should the ingestion of strawberries cause an urticaria in some people? Why should not quinine, belladonna, and other drugs cause rashes in all instead of a few? And again, why should an anacidity of the gastric juice cause in some an eczema, an erythema, or an acne, and be the only manifestation of such a disturbed state of the system, whereas in others there are no skin lesions but marked subjective sensations? We may attempt an explanation of all this, but when all is said and done an answer but begs the questions.

But at any rate the necessity of a routine examination of all skin patients is incumbent on those who attempt to treat them, and it is my intention, by taking up a few of the common dermatoses, to show its importance and to demonstrate the prompt relief that is afforded when the disturbing states are removed.

One of the most universal of the diseases of the skin the practitioner is called upon to treat is acne, and it is claimed that there are very few persons who do not suffer from it to a greater or lesser degree during adolescence. Gilchrist claims that the acne bacillus is the direct cause of the disease and that the constitutional symptoms so often found in association with acne are a result and not a direct etiological factor. Other observers lay stress on staphylococci and streptococci. Be this as it may, there is no doubt that a depraved condition of the system, if not an exciting factor, is, at least, potent in aggravating the disease and in retarding a cure. The disturbances of the general health which favor the development of the disease are anemia, constipation, menstrual disorders, digestive disturbances, malnutrition, local irritations, etc. Of digestive disturbances, that of anacidity is the most frequent (40 per cent. of all cases), and prompt disappearance of the acne is produced by the internal use of hydrochloric acid, solely, when this disorder exists. It must be remembered that subjective symptoms of gastric disturbances are not often complained of, which demonstrates the necessity of the physician's determining the presence or absence of hydrochloric acid for himself. But apart from the organs and portions of the body already alluded to above, there are others that merit close attention. The great power for acne, of the mouth, throat, and nose is least appreciated. Murray[1] as far back as 1899 directed the attention of the profession to unilateral and bilateral erythematous and acneiform eruptions occurring on the face, which were cured speedily by removal of associated pathological conditions of the nose, usually spurs. Diseased conditions of the tonsils are capable of producing erythemas and acnes, and I have known such diseases to prove rebellious to all local treatment until unmistakable disease of the tonsils caused the latter's removal, whereupon the disease of the skin spontaneously disappeared. Holland's[2] recent experiences will help to confirm the fact of the disease-producing powers of abnormal tonsils. Unhealthy conditions of the mouth are also to be taken into consideration. Of these pyorrhea alveolaris deserves most attention. While the scientific dermatologist has long appreciated the power of this disease in causing acnes and other skin diseases, either primarily or secondarily, labor should now be doubled by the report of Dr. Chaplin[3] of Savannah, Ga., who accidentally cured a case of that most resistant of all the chronic inflammatory dermatoses, psoriasis, by specific treatment of a pyorrhea in a psoriasitic. Since the publication of his article two more apparent cures of psoriasis have been reported in the Cincinnati *Lancet-Clinic*, in both of which cases there was a Riggs' disease present in addition to psoriasis. This does not mean, however, that every case of psoriasis can be cured by emetine, but it does go to show the power for ill that diseased states of the mouth have upon the skin.

Besides the upper air tract and the parts already discussed, the state of activity of the kidneys should be taken into consideration. A careful perusal of Bulkley's[4] article will help prove its worth. Should an examination of all these parts throw no light on the possible etiology of the disease there are other avenues left open before we give up the ghost and confess our ignorance of proper therapeusis by saying the disease will disappear in time. True, it does so in the majority of cases, but cases of over twenty-five years' duration are by no means rarities. If we cannot institute appropriate internal treatment we can at least direct local medication with good results if such medication is intelligent. What treatment is best is, of course, a matter for the physician to determine; it is my purpose here to try to impress upon the reader the importance of deranged constitutional conditions in relation to acne, which disease is curable, opinions to the contrary notwithstanding.

Urticaria is another disease that is common and often does not receive intelligent treatment. The ascribed causes of this disease are indeed many. It may be caused by local irritation, by remedial agents externally and internally administered, by foodstuffs, etc. Recent studies tend to show that urticarias resulting from internal causes are for the most part due to the presence of betaimidozolylethylamin, which is formed in the intestinal canal as a result of decomposition of protein foods. While it is true that certain individuals are extremely susceptible to attacks on the least provocation, it is perfectly possible to lessen this susceptibility and prevent recurrences of the disease. To do so it is necessary for the physician to give his patient the same time, study, and careful attention as he would a case of typhoid fever. Whatever perversion of metabolism the examination reveals should be remedied. If the urticaria seems dependent upon an anacidity it is to be cured in this way. Defective elimination, disturbances of the liver, of the nose, mouth, kidneys, etc., should all be sought for. The majority of attacks will, it is true, respond quickly to a hypodermic injection of adrenaline-chloride solution, but we are not doing our best toward the patient unless we prevent further at-

tacks. It is claimed, and is generally true, that the most rebellious urticaria is cured if the patient abstains from albuminous food for two weeks, the diet consisting of tea, coffee, lemon juice, grape juice, potatoes, green vegetables, rice, cereals, bread and butter. After the expiration of two weeks the proteid diet is gradually resumed. While it is hard to impress upon a patient the necessity of such a diet, a careful explanation of the reasons why it is instituted, and a careful writing out of the foodstuffs permitted, rather than a cursory recital of them, will work wonders. There are indeed some cases that defy the most careful and scientific treatment and for which no etiological factor can be ascertained, but these cases are relatively few; and if absolute freedom from the disease cannot be obtained, at least lessening of the number and the intensity of the attacks is most always possible. It is such cases as the latter in which we fall back on an acknowledgment of our ignorance by stating that they are neurotic in type. It is true that urticaria sometimes depends on the presence of nervous disease such as hysteria, and that reflex nervous factors such as phimosis, rectal worms, etc., may be etiologic factors, but careful examination of all patients will, most often, demonstrate a pathological condition for the disease's presence, which will lessen the great number of the so-called nervous types.

And now a few words concerning that most prevalent of all skin diseases, namely, eczema. Constituting 30 or 40 per cent. of all diseases of the skin, it is necessarily the one which we are most often called upon to treat. If practitioners, or specialists even, were curing this affection, so many so-called eczema cures would not be advertised and sold. Extensive treatises have been written upon it, and are still being written, but the last word has not yet been said. Any modern work on diseases of the skin will devote at least five or six pages to its etiology with four or five times that many to its treatment, but all summed up, the etiology of the disease is often obscure and its treatment difficult, sometimes impossible in the present state of our knowledge. What has been said concerning acne and urticaria also applies to eczema, as the same factors causing these diseases are just as capable of causing an eczema. A fact that needs be impressed on the ordinary practitioner is that infantile eczema is practically always a manifestation of a metabolic disturbance, and while local treatment may be used as an adjunct, it is in no way curative. Many dermatologists send their young patients to the pediatrist who, after regulating the diet, returns them. This method of treatment can well be copied by those unfamiliar in solving the exact dietetic disturbance that is causing the skin lesions of their infant patients. Another fact to be borne in mind is that drugs very often cause eczema and other skin diseases. A recital of them is unnecessary, but if we form the habit of asking every patient whether or not he has been taking drugs we shall not so often err in diagnosis or mistake the proper treatment. I am thoroughly convinced that gastric examination of all patients suffering from eczema is to be recommended. A majority suffer from anacidity, some from hyperacidity. I have known one patient to travel the rounds of doctors and specialists alike and to be pronounced incurable. Examination of her stomach contents revealed hyperacidity. Upon the administration of 5 gr. of sodium bicarbonate after each meal for two weeks the eczema disappeared, without any local treatment whatsoever. I have also known skillful men to prescribe, to no avail, treatment for eczemas due to diabetes. You may imagine their shame and chargin when the necessity of urine examinations was gently but forcibly impressed upon them by some doctor whose fame was but a tiny star compared to theirs. I have also known eczema of years' duration to be dependent upon a diminished output by the kidneys, remediable easily after the cause was ascertained. Therefore, the necessity of chemical examinations should no longer be urged. Occupation is also a question that should be asked, for I know of patients who have traveled the rounds and cure was not obtained because the cause was not removed. I may cite Pusey's case of the lady who took an interest in gardening and whose eczema of the hands was found to be due to poisoning by primroses. With the occupational forms of eczema we are all more or less familiar—the necessity of either proving or disproving occupation as a factor needs always to be considered. Often cases will come to our attention that are indeed baffling, and seemingly incurable. There is always a cause, however, which we may or may not be able to determine. No one would think that a displaced kidney was capable of producing persistent eczema, but that such is so is proved by Abramitcheff who reports such a case cured by wearing a suitable belt; furthermore, the eczema always recurred when the belt was removed. My friend Dr. Dobson of South Carolina has told me of a case of chronic eczema of years' duration which was cured by the removal of an appendix operated upon because of an acute exacerbation of what was evidently a chronic process, not producing symptoms. Such rare cases may be recited *ad infinitum*, but the moral to be learned from them all is that a painstaking examination will, in the majority of cases, throw light upon what we now regard as a dark subject.

I have tried to make plain the pitfalls we encounter in treating diseases of the skin. And I reiterate the necessity of thorough examination of all patients suffering from such diseases—even at the risk of being considered an extremist. Skin complaints are very serious matters for patient and physician alike, and if we considered enough the mental wretchedness of such patients, probably pity would enter our souls and stimulate us to do the very best that is in our power for them, instead of temporizing with uncertain remedies. The dermatoses do not kill of themselves, it is true, but they make life miserable, almost unbearable. And, finally, I wish to make a plea for more research work in connection with these diseases. Practically the only advance we have made in this field of endeavor has been in diagnosis, but diagnosis is of passing moment to the patient. What we need is specific therapeusis, and this we can obtain only by research.

DIFFERENTIAL DIAGNOSIS BETWEEN CEREBRAL HEMORRHAGE AND SOFTENING DUE TO THROMBOSIS.

By GORDON BURKE, M.D.,
AND
JOHN NUZUM, M.D.,
CHICAGO.
INTERNS AT THE COOK COUNTY HOSPITAL.

A. C., an American housewife, 66 years of age, was brought to the ward in coma. A friend said she had been found unconscious on the floor of her room two days previously and had remained so ever since. No further history could be obtained.

Physical examination showed a well preserved white woman, lying in deep coma; respirations stertorous; pulse about 100; systolic blood pressure 170, diastolic 100. There was conjugate deviation of the eyes and head to the right with paralysis of left side of the body and face. Right pupil reacted to light and accommodation; left pupil was fixed; ptosis of the left upper lid. Reflexes were present and normal on the right side of the body, except the abdominal, but all were absent on the left side. Babinski, Oppenheim, Chaddock, and Gordon signs were all absent. Coarse bubbling râles were heard over both lungs posteriorly and over upper lobes anteriorly. Heart was a little enlarged and slightly arrhythmic.

Spinal puncture revealed a murky red fluid under normal pressure, tending to become clearer. Blood showed 19,000 white cells with normal differential count. Urine had a specific gravity of 1.022 and showed a large amount of albumin with a moderate number of epithelial and pus casts, many hyaline and granular casts, and some epithelial and pus cells. No sugar or blood could be detected.

During the two days following entrance and preceding death the temperature rose to 103.8° with pulse staying relatively low. Respirations went to 40 a minute. A divergent strabismus developed which later became a conjugate deviation once more. Blood pressure rose to 210 systolic and 120 diastolic. The rest of the findings, such as reflexes, etc., remained the same. The patient continued in deep coma, though with purposeless movements of right arm and leg, until her death on the third day after entrance. Diagnosis was "Cerebral hemorrhage."

Postmortem examination showed a thrombosis of the right midcerebral artery with an area of softening involving the region of the basal ganglia in the posterior limb of the internal capsule and the inner and lower part of the occipital lobe. In addition there was a marked nodular syphilitic arteriosclerosis most marked in the descending thoracic aorta where there were several islands of ulceration. Just above the bifurcation of the aorta senile arteriosclerosis was found. There was a marked hypertrophy of the left ventricle with an acute fibrinous pericarditis and a moderate amount of fluid.

The deep coma, high blood pressure with high tension pulse, conjugate deviation of the eyes and head, elevated temperature, hypertrophy of the left ventricle (as shown also by the autopsy), and the presence of albumin and casts in the urine—all these findings are considered typical for cerebral hemorrhage, which therefore had to be diagnosed in this case. No adequate history having been obtainable, the diagnosis was made from the clinical picture alone. Yet the postmortem examination showed brain softening due to thrombosis of the right middle cerebral artery.

It seems evident that the differential diagnosis between cerebral thrombosis and hemorrhage is in many cases impossible and can be made with only a slight degree of probability.

Bacteriology of Gastroduodenal Ulcer.—Rosenow and Sanford find good evidence that streptococci are not merely accidental secondary invaders of the tissues, but are commonly the original cause, as well as the important factor in preventing the healing of the ulcer. —*Journal of Infectious Diseases.*

Medicolegal Notes.

Hypothetical Question—Insufficiency.—In an action for the death of a passenger who, suffering a stroke of apoplexy while on a street car, was carried thereon for five hours, hypothetical questions were put to medical experts, on which they gave the opinion that had the plaintiff's intestate had proper care within one or two hours after his first attack his life could have been saved. The questions assumed that the deceased was in good condition, or apparently in good condition, on boarding the car, and contained no reference whatever to conditions shown by the plaintiff's witnesses to have existed, especially to the hardened condition of his arteries and the condition of his kidneys indicated by the presence of albumen and granulated casts in his urine. It was held that the omission was error.—Middleton vs. Whittridge, New York Court of Appeals, 108 N. E. 193.

Authentication of X-Ray Photograph.—In an action for damages for injury to a hand crushed by a wagon a medical witness for plaintiff produced an *x*-ray blueprint, and, in reply to the question whether it correctly showed the position of the fingers in the palm of plaintiff's injured hand at the time of trial, said that it explained the reason of the deformities he had found. It was held that the admission of an *x*-ray blueprint to show the part of the hand injured, without other evidence that an *x*-ray picture was taken of plaintiff's hand or that the one produced was a picture of the hand, was incompetent and, in view of the large verdict of $1,500, reversible error.—Kossoff vs. Kufferberg, New York Appellate Division, 154 N. Y. Supp. 149.

Practising Medicine—Holding Out as Being Able to Diagnose or Treat Diseases.—New York Public Health Law (Consol. Laws, Chapter 45) section 160, subdivision 7, defines the "practice of medicine" as consisting in holding one's self out as being able to diagnose or treat human diseases and offering such treatment, and section 174 makes one practising or advertising the practice of medicine under a name other than his own guilty of a misdemeanor. A duly registered physician, who transacted business under the duly adopted trade-name "The Standard Pharmacy Company," and at whose office a caller was examined, given a prescription, filled and paid for at the desk, without charge for the medical service, and whose office contained signs indicating that he was engaged in the manufacture of certain remedies, that he employed a consulting physician to whom patrons might go for free medical advice, whose booklet of advertisements contained a coupon for consultation and free advice, and whose cards for free examination, inscribed "Medical and Surgical Office of the Standard Pharmacy Company," requested its physician to make examination and give medical advice to the bearer without charge, was held to be practising medicine unlawfully by holding himself out under his trade-name as able to diagnose and treat diseases, and as offering and undertaking to do so.

The Court said: "This factor of holding out apparently underlies all the important cases in which the defendant has been held for violation of the law. There have been laid before me, without objection, by the respective counsel, extracts from the record in these cases. In People vs. Woodbury Dermatological Institute, 192 N. Y. 454, 85 N. E. 697, the advertisements announced that 'the Woodbury method succeeds, because it entirely removes these dead cells;' 'we perfect baggy skin;' 'we correct unshapely noses,' etc.; 'we remove freckles,' etc.; 'by methods of our own, we extract these dead cells;' 'all remedies prescribed by us are scientifically prepared in our private laboratories.' In the case of People vs. Doctor Weeks Medical Institute, 126 Appellate Division, 950, 111 N. Y. Supp. 1134, in which the judgment against the defendant below was affirmed on the authority of the Woodbury Case, 124 Appellate Division, 877, 109 N. Y. Supp. 578, the advertisements read: 'We treat all private and chronic diseases;' 'we cure by the best of medical ability;' 'Dr. Weeks' Medical Office, specialist for nervous and chronic diseases;' 'we cure all cases we undertake.' In People vs. Samuel Gross, decided in the Court of Special Sessions in November, 1911, the defendant was the proprietor of an institution known as the Workingmen's Medical Aid Society. One of the circulars contained the statement: 'It is the object of the Workingmen's Medical Aid Society to furnish reliable medical service to members and their families.'"—People vs. Warden, New York Appellate Division, 152 N. Y. Supp. 977.

RHEUMATIC HEART-BLOCK.

THE interruption in the conduction paths of the heart leads to total heart-block, which in most instances is ushered in by the Adams-Stokes symptom-complex. The condition may be permanent or temporary, depending upon the anatomical substratum. If gummata, tumors, scars, fatty infiltrations, or calcium deposits occur in the region of the conducting system, a complete restitution to normal is not conceivable. On the other hand, there may occur transient leucemic or acute inflammatory infiltrations of the myocardium which may give rise to a heart-block that is similarly transient. To this type belongs the so-called rheumatic heart-block which is caused by the presence of the small-celled infiltrations known as Aschoff's bodies in the region of the conducting bundles. These bodies may be disseminated throughout the myocardium. Rheumatic myocarditis is almost always associated with an endocarditis.

Disturbances of the conducting mechanism of the heart during the course of a rheumatic myocarditis are not extremely uncommon. Instances have been reported by Gerhardt and others. Of great rarity, however, are the cases of total heart-block occurring in the course of acute articular rheumatism. The first recorded case was that described in 1905 by Mackenzie; the condition was transitory. Of extreme interest is the case reported by Cowan, Flemming and Kennedy. The patient was a young woman who complained of pains in the joints and in whom a sudden onset of heart-block was soon followed by death. At autopsy foci of round cells were found in the bundle of His. A similar case was that reported by Pardee, with the chief difference that a febrile rheumatic attack of three months' duration preceded the rapidly fatal incidence of heart-block. Of the five undoubted cases of rheumatic heart-block so far reported, three resulted in death. In none of the cases was the typical Adams-Stokes syndrome observed, although with the onset of the bradycardia there occurred dizziness, malaise, dimness of vision, and other symptoms of cerebral anemia.

An exhaustive review of this entire subject is presented by Tibor von Podmaniczky in the *Zeitschrift für klinische Medizin*, Vol. 82, Nos. 1 and 2. He also reports two interesting cases of his own. The first was that of a soldier twenty-two years of age who entered the hospital one week after the onset of an attack of acute articular rheumatism. Six days later as he was getting out of bed he suddenly became dizzy, "saw black before his eyes," and experienced a sensation of disconfort in the region of the heart. The symptoms lasted for only a few minutes. Physical examination made immediately afterward showed, in addition to a slight cyanosis of the lips and finger-tips, a radial pulse of 32 and a jugular pulse of 94. The following day the inequality disappeared.

This was a case of transient rheumatic heart-block, comparable with those reported in the literature, but not presenting the complete classical picture of the Adams-Stokes syndrome. The latter is always associated with a distinct danger to life, for according to Hering, the attacks of syncope, apnea, and epileptiform convulsions occurring in this symptom-complex are the result of a temporary cerebral anemia. During the transition from the normal cardiac action to the condition of heart-block there is a stage of complex cessation in the activity of the ventricle before its automatic contractions are again established. This pause has been observed to last as long as thirty seconds. In the above case the atropine test was not performed, nevertheless, the assumption is made that the heart-block was the result of a toxic action on the vagus, for the author cannot conceive of any anatomical lesion of the conducting system causing such a fugitive train of symptoms as was present in this case.

The second case reported by von Podmaniczky presents a number of points of special interest, particularly when contrasted with the first case. The patient was a soldier twenty-nine years old, whose cardiac symptoms were first manifested ten years previously after a severe attack of tonsillitis. These symptoms were dyspnea on exertion, palpitation, and sensitiveness to cold. A valvular lesion was recognized at that time. One year before he came under the author's observation there was a marked increase in the intensity of the patient's symptoms, to which were added a sense of constriction and attacks of pain in the precordial region. The patient was then told that he had bradycardia. His condition continued without any apparent change until the time of the present study. The most significant physical sign was a radial pulse of 40 associated with a jugular pulse of 70 to 80. *X*-ray examination confirmed the diagnosis of heart-block whose rheumatic origin was strongly suggested by the history, the presence of a diastolic murmur at the apex, and a negative Wassermann reaction. Polygraphic studies showed a dissociation between auricles and ventricles. The atropine test was negative on repeated trials. There was no question that this was a case of persistent and complete heart-block. There was presumptive evidence that this was of rheumatic origin, and that it developed gradually. The Adams-Stokes syndrome was, however, at no time present. The author conceives of the pathological picture as of one comprising the presence of Aschoff's nodules localized to the region of the bundle of His, or of cicatricial changes in the same

region. The latter would be indicated by the long duration of the condition.

The author believes that the latter case is the first recorded instance of total persistent heart-block of rheumatic etiology. Its chief interest is apparent when it is compared with the first case. There is a striking parallelism between the two clinical pictures as regards the rheumatic origin, the organ affected, and the functional disturbances of the latter. The differences between the two pictures are also equally pronounced. Of prime importance to the patient, however, is the prognostic outlook, which in the one case is relatively good and in the other is extremely bad.

INSANITY AND THE WAR.

THE horrors of war from every conceivable standpoint have been vividly pictured during the past year. From the aspect of public health it was pointed out that in war it is not the survival of the fittest but the survival of the most unfit. It is the flower of the race that is stamped out or deprived of, the faculty ever to bloom again. It is the weeds, at any rate physicially, that are left. A nation which loses its best in war necessarily deteriorates, for those who are left are deficient in vitality and are unable to reproduce a sturdy stock.

In the *Lancet*, Sept. 4, 1915, the question is treated editorially from another and more optimistic point of view. It is generally held that the experiences of war as now waged, the strain exerted on the nervous system of continual shell concussions while one is cooped up in a trench, must have the effect of bringing about grave psychological disturbances not infrequently terminating in insanity and neuroses. But the question may be asked, is such really the case? And does war leave behind it enormous wreckage in the guise of nervous and mental sufferers, more or less permanently incapacitated and uninfluenced by treatment?

The writer in the *Lancet* states that facts do not support this point of view and bases his contention upon the recently published Eighty-fifth Annual Report of the Belfast District Lunatic Asylum in which the superintendent, Dr. Graham, refers to the remarkable decrease in the number of admissions for the year as compared with the twelve months preceding. He declares that in such a time of upheaval as the present it is natural to suppose that mental suffering ending in brain collapse should be the order of the day, whereas the figures do not bear out the suggestion. He further holds that "it is not the great tragedies of life that sap the forces of the brain and wreck the psychic organism. On the contrary, it is the small worries, the deadly monotony of a narrow and circumscribed existence, the dull drab of a life without joy and barren of achievement, the self-centered anemic consciousness; it is these experiences that weaken and diminish personality and so leave it a prey to inherited predispositions, or to the slings and arrows of outrageous fortune."

EFFECT OF PITUITARY EXTRACT UPON THE SALIVARY SECRETION.

ALTHOUGH the influence of an extract of the posterior lobe of the hypophysis upon the circulatory system has been fairly well established, the effect of this extract upon the process of secretion is still a matter of dispute. Some observers note that the secretory changes are to be accounted for by the accompanying vascular effects, while others maintain that there is a direct action upon the secreting cells. The problem is one of profound interest in pharmacology as well as in physiology. An important step toward its solution is provided by the results of an investigation conducted by G. O. Solem and P. H. Lommen (*American Journal of Physiology*, September 1, 1915), who studied the effects of the extract of the posterior lobe of the hypophysis upon the secretion of saliva.

The above investigators find that pituitary extract causes a diminution in the flow of blood and saliva from the submaxillary gland. The decrease in the flow of saliva is greater than the accompanying decrease in the blood flow. The slowing of blood is less marked if the injection is made during faradization of the chorda tympani than during pilocarpine stimulation, while the slowing of saliva is the same. Pilocarpine is relatively ineffective even when injected seven or eight minutes after pituitary extract. While suprarenal extract normally causes a vasodilatation in the gland (contrary to its action on the vascular system in general) and an increase in salivary secretion, the substance, during the action of pituitary extract, has the normal effect on the blood flow, but causes a diminution in salivary flow, probably owing to the greater quantity of pituitary extract coming in contact with the gland. When pituitary extract is injected during the action of chrysotoxin the decrease in the flow of saliva sets in before the vasoconstriction in the gland occurs. In five out of seven cases the flow of saliva slowed while there was active dilatation of the gland.

From the above results the general conclusion is drawn that the decrease in flow of saliva following the injection of pituitary extract is due to an inhibition of the action of the secretory nerves of the submaxillary gland, but also in part to the accompanying vasoconstriction caused by direct action on the muscle of the arterioles, on the vasomotor nerve endings, or on both. The decrease in output of blood from the gland may also be due to the decreased activity of the gland.

INTRAVENOUS INJECTION OF DIPHTHERIA ANTITOXIN.

IDEAL for the treatment of diphtheria, according to Seidel, is the following combination: earliest possible injection of antitoxin, large dose, and intravenous route—not alone but in association with the usual intramuscular injections. If treatment is instituted within the first three days the prognosis is good, varying with the duration; but after the third day all is reversed and any selection due to the treatment is abolished. At a recent meeting of the Medical Section of the Scientifico-Medical So-

ciety of Jena (*Munchener medizinische Wochenschift*, June 29) Seidel saw in a given material 100 per cent. recoveries in cases injected before the third day and 100 per cent. mortality in all injected after this period. In one case he saw complete defervescence follow at once upon an intravenous injection of serum. In the discussion of his paper Reichmann stated that with the use of the intravenous route he had not lost a case of diphtheria in nine months. The relative merits of high and deep tracheotomy were discussed, but intubation was not even mentioned. It will some day be rediscovered in Germany and will then become the accepted method of treatment of laryngeal stenosis in that country.

Icterus and Picric Acid Poisoning.

THE frequent therapeutic use of picric acid chiefly as an external application has given rise to an occasional instance of poisoning by means of this drug when taken internally by accident or with suicidal intent. The toxic dose for a human being is four to five grams; the lethal dose is not known. The symptoms caused by the absorption of picric acid are a yellowish coloration of the skin and mucosæ, gastrointestinal irritation, prostration, and a change in the color of the urine which resembles that seen in catarrhal jaundice. Owing to the close similarity between the objective evidences of picric acid poisoning and those of the various types of jaundice, the differential diagnosis between the two is a subject of no little practical importance. This furnished the theme for an experimental investigation by Marcelle Wahl (*Presse Médicale*, August 5, 1915). He found that there is no means of making an absolutely positive differential diagnosis between the two conditions. The absence of biliary pigments in the urine would be strong presumptive evidence in favor of an apparent icterus being caused by the absorption of picric acid. Chemical analysis of the urine fails to be of any service in the above differentiation, owing to the fact that almost all of the picric acid absorbed is eliminated in the urine in the form of derivation products.

Total Color Blindness.

ACCORDING to the very plausible view of Kriess a subject with total color blindness is a "rod seer"; that is, he has failed to develop the retinal cones which alone make possible color vision, and his visual perceptions are due solely to the retinal rods. Instead of color he perceives only tones. To bear out this theory histological studies are necessary, and it is seldom indeed that the eye of a totally color-blind subject can be obtained either at autopsy or as a result of enucleation. At a meeting last May of the Naturwissenschaft-medizinische Gesellschaft of Jena (*Münchener medizinische Wochenschrift*, June 1) Hegner reported two cases of total color blindness in one family, the other children of which had normal vision. As is common in such cases the eyes were otherwise defective. After astigmatism had been duly corrected by glasses vision was only five thirty-fifths. There was lively nystagmus as well as photophobia. The fundus was normal and there was no central scotoma. The typical displacement of the distribution of lightness from yellow to green could be demonstrated, as could also the notable shortening of the spectrum at the long wave end.

News of the Week.

New York City Death Rate.—During the week ended October 9 there were 1,250 deaths in this city, giving a rate of 11.32 per thousand, as compared with a rate of 11.53 for the corresponding week of last year. The rate for the first 41 weeks of 1915 was 13.31, as compared with 13.75 for the corresponding period of 1914.

Chicago Death Rate.—During the week ended October 9 there were 606 deaths in Chicago, giving a rate of 12.9 per thousand, as compared with 574 deaths and a rate of 12.5 for the corresponding week of 1914.

Cholera is reported to have been discovered among the German sailors in Kiel, the disease having been brought to that place by the Russian prisoners.

Typhus Fever is said to be epidemic in Victoria, Australia, 447 cases and 134 deaths having occurred up to October 9, according to a dispatch from Melbourne.

American Red Cross in Germany.—The members of the American Red Cross working in Germany and Austria were relieved from duty on October 1, their hospitals being closed. Most of them, however, both surgeons and nurses, have volunteered to look after the German prisoners in Russia, there being a scarcity of German army surgeons there. The Russians complain that the Teutons do not send their own surgeons to care for the wounded prisoners which the Russians have taken. Upon the completion of the American Red Cross work in Germany and Austria the members received decorations from the respective governments.

The American Red Cross at Belgrade.—Three times has the American Red Cross unit sent to Serbia a year ago been under fire at Belgrade, and, according to a cablegram transmitted from Vienna to the Red Cross headquarters in Washington, it is still there. Dr. Edmund W. Ryan of Scranton, Pa., chief of the unit, cabled: "We are still in Belgrade, working. Everybody well. Notify families of personnel." It was intended that they should leave on October 1, but the new invasion of Serbia made more work for them, so they have remained.

The Scarcity of Drugs in this country is becoming very serious, and if prices continue to soar the therapeutic nihilists will perforce have it all their own way; there will indeed be few drugs to give the sick unless we resort to the native specifics of the Eclectics or the high potencies of the Homeopaths. The German synthetics are about used up and no more are to be had at any price, but many other drugs are also unobtainable. A number of these are made from plants grown chiefly in Europe or Asia, and in the case of others the demand for them by the belligerent nations is so great as to make their cost here almost prohibitive. Speculation is said also to have had an influence in raising prices. Crude codliver oil has doubled in price, glycerin has nearly trebled in value, the cost of quinine is about six times what it was a few months ago, and the price of senna and many other crude drugs has risen in proportion.

Medical College Consolidation.—It is authoritatively reported that negotiations are in progress for the consolidation of the Medico-Chirurgical College of Philadelphia with the University of Pennsylvania, the purpose being to make the former the graduate department of the latter.

American Medical Editors' Association.—The 46th annual meeting of this Association was held at the Hotel McAlpin, New York, on Monday and Tuesday of this week under the presidency of Dr. H. Edwin Lewis of *American Medicine*. There was a large attendance and many papers were read and discussed. On Tuesday the annual banquet took place, the president being toastmaster. The election of officers resulted in the choice of the following: *President*, Dr. E. C. Register of the *Charlotte Medical Journal; First Vice-President*, Dr. W. A. Jones of the *Journal-Lancet*, Minneapolis; *Second Vice-President*, Dr. G. Morris Piersol of the *American Journal of the Medical Sciences*, Philadelphia; *Secretary and Treasurer*, Dr. Joseph MacDonald, Jr., of the *American Journal of Surgery*, New York; *Executive Committee*, Drs. C. F. Taylor of Philadelphia, John C. MacEvitt of Brooklyn, and A. S. Burdick of Chicago; *Publication Committee*, Drs. H. Edwin Lewis of New York, C. E. de M. Sajous of Philadelphia, Charles Wood Fassett of St. Joseph, Mo., and Robert M. Green of Boston.

"The Journal of Laboratory and Clinical Medicine."—We have received the first number of this journal, published in St. Louis, under Dr. Victor C. Vaughan, as editor-in-chief. The purpose is stated to be "to bring discovery and its application closer together, to supply the research man with a strictly scientific organ through which he can report the result of his labors, and to suggest to the practitioner how he may use the latest discoveries." It is an attractive publication, with an able editorial staff, and the character of its contents gives promise of permanence as well as high quality in the future.

Dr. Carl Anton Ewald, editor of the *Berliner klinische Wochenschrift*, died on September 20 at the age of 70 years. He was widely known as an authority on diseases of the digestive organs. He was also for a quarter of a century librarian of the Berlin Medical Society.

Dr. Harold Kneist Faber, formerly of the Rockefeller Institute, New York, has been appointed assistant professor of pediatrics at the Stanford University Medical School, San Francisco.

Dr. Howard Hepburn, formerly medical superintendent of the Montreal General Hospital, now serving in one of the British field hospitals in France, has been promoted to the rank of captain in the medical corps.

Dr. J. H. Frazer has been made dean of the School of Medicine of the University of Alabama at Mobile, succeeding Dr. Eugene D. Bondurant, who has resigned on account of ill health. Dr. Frazer was for many years treasurer and secretary of the school and also professor of obstetrics. The fifty-seventh session of this school began on September 30.

Dr. John C. Feltz, assistant to the medical director of the State Hospital for the Insane at Schenectady, N. Y., has resigned and will make his home at Gettysburg, Pa.

Dr. Frank A. Hartman, formerly of the Harvard Medical School, has been appointed lecturer on physiology at the University of Toronto.

Dr. William Hanna Thomson of this city has removed to 71 Central Park West.

Dr. John N. West has been elected president of the Ohio Society of Philadelphia.

Dr. E. B. Funkhouser has been appointed assistant to the medical director of the State Hospital for the Insane at Schenectady, N. Y., to succeed Dr. Feltz, resigned.

Medical Society Elections.—The Medical Society of the State of Pennsylvania, at its recent meeting in Philadelphia, elected the following officers: *President*, John B. McAlister, Harrisburg; *President-Elect*, Charles A. E. Codman, Philadelphia; *First Vice-President*, J. Torrance Rugh, Philadelphia; *Second Vice-President*, Edgar M. Green, Easton; *Third Vice-President*, W. Albert Nason, Roaring Spring; *Fourth Vice-President*, Meyers W. Horner, Mt. Pleasant; *Secretary*, C. L. Stevens, Athens; *Assistant Secretary*, C. P. Franklin, Philadelphia; *Treasurer*, George W. Wagoner, Johnstown. The next annual meeting will be held in Scranton.

The Association of Military Surgeons of the United States, at its meeting in Washington in September elected the following officers: *President*, Surgeon General Rupert Blue, U. S. Public Health Service; *Secretary*, Lt.-Col. Edmund L. Munson, Medical Corps U. S. Army. The next meeting will be held in Chicago.

The Utah State Medical Association, at its meeting in Salt Lake City the last week in September, elected the following officers: *President*, E. W. Whitney, Salt Lake; *First Vice-President*, L. B. Baker, Eureka; *Second Vice-President*, C. F. Osgood, Ogden; *Third Vice-President*, Fred Dunn, Springville; *Secretary*, W. Brown Ewing, Salt Lake; *Treasurer*, H. P. Kirtley, Salt Lake. The next meeting will be in Salt Lake City in October, 1916.

The Talladega County (Ala.) Medical Society, at its quarterly meeting at Chocco Springs, October 5, elected the following officers: *President*, Dr. F. H. Craddock; *Vice-President*, Dr. S. W. Welch; *Censor*, Dr. C. L. Salter; *City Physicians:* Talladega, Dr. S. W. Welch; Sylacauga, Dr. French Craddock; Ironaton, Dr. Fennell; Munford, Dr. Harris; Talladega Springs, Dr. Moore; Gantt's Quarry, Dr. Batson; Lincoln, Dr. McLaurin.

The Brookline (Mass.) Medical Club, at its meeting on October 4, elected officers as follows: *President*, Dr. C. R. C. Borden; *Vice-President*, Dr. Harold Walker; *Secretary and Treasurer*, Dr. Harold Bowditch.

The Wisconsin State Women's Medical Society, at its annual meeting in Milwaukee on October 5, elected the following officers: *President*, Dr. Mary Piper Houck, La Crosse; *Vice-President*, Dr. Minnie Hopkins, Oconto; *Secretary*, Dr. Ada Chandler, Pardeeville; *Treasurer*, Dr. Chaffee Fay, Whitewater; *Members of the Board of Censors*, Drs. Belle Nair, Oshkosh, and Mary Fitzpatrick, Milwaukee.

The Norfolk County (Va.) Medical Society, at its annual meeting on October 4, elected the following officers: *President*, Dr. J. J. Miller; *Vice-President*, Dr. R. S. Kight; *Secretary-Treasurer*, Dr. W. P. McDowell.

National Committee for the Prevention of Blindness.—The first annual meeting of the National Committee for the Prevention of Blindness will be held in the assembly room of the Russell Sage Foundation building, corner of East Twenty-second Street and Lexington Avenue, New York, at 4.30 P.M., Nov. 4. Ex-President William H. Taft will be present and will speak, and Dr. G. E. de Schweinitz of Philadelphia will make an address.

Obituary Notes.—Dr. James W. Mitchell of Atlanta, Ga., a graduate of the Southern Medical College, Atlanta, in 1880, died at his home on October 1.

Dr. John Tyndall Gibbons of Brooklyn, N. Y., a graduate of the College of Physicians and Sur-

geons, New York, in 1889, consulting physician to the Home for the Blind, and a member of the Association of Military Surgeons of the United States and the Brooklyn Medical Society, died at his home from heart disease, on October 2, aged 50 years.

Dr. JOHN H. ASHCRAFT died at Mullica Hill, N. J., on September 26 at the age of 82 years. He was graduated from Jefferson Medical College in the class of 1855.

Dr. G. T. PRINCE of Chattanooga, Tenn., a graduate of the University of Tennessee, Medical Department, Nashville, in 1887, died at his home in St. Elmo, Chattanooga, after a brief illness, from acute indigestion, on September 16, aged 50 years.

Dr. JOSEPH HORMISDAS BOUCHER of Woonsocket, R. I., a graduate of Laval University, Medical Department, Quebec, in 1884, formerly a member of the State General Assembly, and prominent in the Democratic party of Rhode Island, died at his home on Sept. 25, aged 57 years.

Dr. LUTHER HERN KELLER of Hagerstown, Md., a graduate of the College of Physicians and Surgeons, Baltimore, in 1875, and a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, the Washington County Medical Society, of which he was a former president, and the Cumberland Valley Medical Association, died suddenly from heart disease while seated in a chair on the porch of the Washington County Hospital, Hagerstown, on Sept. 30, aged 63 years.

Dr. HARRY OLIVER LIGHTNER died at Maryville, Pa., on Oct. 5 at the age of 43 years. He was graduated from Baltimore Medical College in the class of 1896.

Dr. JOHN GAUNT BROOKS of Paducah, Ky., a graduate of the Jefferson Medical College, Philadelphia, in 1868, formerly city physician of Paducah and member of the City and County Health Boards and the Board of Education, a charter member and one-time president of the Kentucky State Medical Association, and a member of the American Medical Association and the McCracken County Medical Society, died in a sanatorium at Louisville, after a short illness, on Sept. 25, aged 75 years.

Dr. R. P. SORRELLS of Danielsville, Ga., a graduate of the University of Georgia, College of Medicine, Augusta, in 1875, died at his home suddenly, on Sept. 25, aged 60 years.

Dr. FLOYD M. YOUNG of Atlanta, Ga., a graduate of the Georgia College of Eclectic Medical and Surgery, Atlanta, in 1887, died at his home from acute indigestion, after a brief illness, on October 6, aged 50 years.

Dr. ROBERT B. BARRON of Gray, Ga., formerly of Macon, a graduate of the Bellevue Hospital Medical College, New York, in 1883, and a member of the Medical Association of Georgia and the Jones County Medical Society, died suddenly at his home on October 2, aged 56 years.

Dr. GEORGE HAMILTON WILSON of Albion, Me., a graduate of the Medical School of Maine, Portland, in 1856, and a former member of the State Legislature, died at the home of his daughter in Waterville, Me., after a long illness, on October 5, aged 86 years.

Dr. SAMUEL K. SPALDING of Omaha, Neb., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1874, and the Bellevue Hospital Medical College, New York, in 1882, a director of the Omaha Theological Seminary, and a trustee of the University of Omaha, died in Washington, D. C., where he had gone to attend the national encampment of the Grand Army of the Republic, on September 29, aged 68 years.

Dr. CHARLES WALLACE STILES of Somerville, Mass., a graduate of the Boston University School of Medicine in 1878, and a member of the Boston Homeopathic Medical Society and the American Institute of Homeopathy, died at his home on October 7, aged 65 years.

Dr. JOSEPH ETIENNE GENDRON of Worcester, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1871, died in St. Vincent's Hospital, Worcester, on October 5, aged 72 years.

Dr. HOMER G. NEWTON of Sherburne, N. Y., a graduate of the New York University Medical College, New York, in 1863, formerly a practitioner in Brooklyn, and one of the founders of the Brooklyn Eye and Ear Hospital, a surgeon in the United States Army during the Civil War, died at his home on October 11, aged 79 years.

Dr. WILLIAM MERRILL MCCOY of Wenatchee, Wash., a graduate of the University of Illinois College of Medicine, Chicago, in 1901, and a member of the American Medical Association, the Washington State Medical Association, and the Chelan County Medical Society, died in the Deaconess Hospital recently, following an operation for appendicitis, aged 39 years.

Dr. WARREN DAVID KLEPPINGER died at Allentown, Pa., on October 9 at the age of 26 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1913. He was pathologist to the Allentown Hospital.

Dr. HENRY WASHINGTON RIHL died at Philadelphia on October 10 at the age of 92 years. He was graduated from Jefferson Medical College in the class of 1849.

Dr. J. GRIER MARPLE, formerly of Harrisburg, Pa., died at Philadelphia on October 10 as a result of nephritis.

Dr. ALBERT S. ERNEY died at Philadelphia on October 12 at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1877.

Dr. JOHN C. PRICE, Chief Medical Inspector of the Division of Hygiene and Engineering of the Pennsylvania State Department of Labor and Industry, died at Camp Hill, Harrisburg, on October 13 at the age of 44 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1893.

Dr. WILLIAM J. MCNAUL died at Philadelphia on October 14 at the age of 43 years. He was graduated from Jefferson Medical College in the class of 1894. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. EDWARD OSBAND SUTTON of Tacoma, Wash., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1903, and a member of the American Medical Association, the Washington State Medical Association, and the Pierce County Medical Society, and for seven years secretary of the last, died in a hospital in Seattle, Wash., on October 1, following an operation, aged 40 years.

Dr. MATTHEW BONNER FLINN, formerly of Worcester, Mass., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1865, died at the home of his daughter in Oakland, Cal., on October 5, aged 72 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

MEDICAL DEFENSE—GONE TO THE FRONT—DRUG TARIFF—OBITUARY.

LONDON, October 1, 1915.

THE annual meeting of the Medical Defense Union was held on September 16. This year the assembly was at Bedford, and although it is spoken of as well attended by some, I can hardly think it satisfactory except by reflecting that medical practitioners are at this time rather fully occupied on account of the war and not a few are absent on military duty. I will not tell you the exact number counted, but merely add that the town and county might, if at all in earnest, have doubled it. The statutory resolutions were passed and the retiring members of council, being willing to continue in office were re-elected and thanked for their past services. The year has been an arduous one, as in addition to the usual work the war has given rise to numerous questions. Several arbitrations have been conducted and the decisions arrived at have been acquiesced in by the disputants who, so far as I hear, have been satisfied. This kind of work bulks largely in the proceedings, but the Union does not engage in law-suits between practitioners. The defence it undertakes is rather to protect medical men from encroachments by the public or individuals under circumstances in which their rights are seriously threatened.

The cases referred to the Union last year numbered 110, of which 36 were in defence of the honor or reputation of members concerned in suits for libel or slander, 22 related to charges of malpractice, 5 to prosecutions for unqualified practice and 47 to personal or miscellaneous matters, such as insurance, partnerships, inquests, terms of appointments and so on. The report of the solicitor shows further that the legal costs for the last fifteen years have amounted to nearly £16,000. The cost per case averaged £174. These few items will suffice to show you that the Union is an important protection for the general practitioner. Nor is it only a defence against actual assaults. Its mere existence is a warning that unjust attacks upon him are not devoid of danger to the assailant.

Many medical men have left their practices and gone to the front. Not a few have arranged with neighboring practitioners to take charge of their patients during temporary absence, on the understanding that they shall not be asked to continue to do so after the return of their usual attendants from the war. The public, to a considerable extent, seem inclined to support this honorable arrangement.

Sir James Barr has been urging that the medical care of the civil population must be held far behind that of our fighting men for whom there still remains a deficiency. He says all home work can be carried on by men over military age, and it is for young men to face the fatigues of a campaign. There must be medical officers for the troops going abroad. He holds it the duty of public bodies not to employ medical men of military age, and he would discharge any they may be employing who are fit for military service.

The drug tariff under the National Insurance Acts gives rise to much discussion which does not appear to promote agreement. A committee was appointed to consider the margin of profit yielded by the present tariff, whether any revision is required, and if so what, whether much change in the list of priced drugs and mixtures is desirable and how far it is practicable to place the tariff on a commercial basis.

The report of this committee, which appears to have devoted much attention to the questions involved, is received with varying degrees of approval or disapproval, but you will hardly care for more than a brief abstract of its conclusions. It declares that revision is required and should provide for payment of (a) the cost of drugs supplied, (b) a flat rate per prescription for establishment and expenses, (c) a fee per prescription for any professional services, graded by the nature of the prescription. Further, it advises a general revision to be undertaken annually and so arranged that the prices of certain drugs can be varied during the year in exceptional cases; that during the war the present plan be continued as it meets the war fluctuations by temporary alterations; that revisions should be undertaken by the central bodies which represent the interests involved, and that all revisions should, as far as possible, be made uniformly applicable to the whole United Kingdom.

As to contracts with chemists it is recommended that they should include an obligation to supply a quality such as would cost about the same as allowed for in the tariff. Also that the pricing of prescriptions should be fixed by insurance committees.

Surgeon F. J. Humphrys, M.D., B.N., died on September 5 of wounds inflicted in the war, at the age of 27. He served in the Dardanelles in the summer and afterwards on the armored car "Squadron."

Dr. Tacey of Bradford, an authority on Woolsorters' disease and able microscopist, has died at 82.

Surgeon-Major R. E. Volunteers G. Robinson, Hon. Surg. Teachers' Orphanage, has died at Bascombe, to which he retired about six years ago.

Surgeon-General Sir Lionel D. Spencer, honorary surgeon to the King, has died at the age of 73. He entered the Indian medical service in 1865 and passed through the several grades, becoming P. M. O. in the Wazeristan Force, 1894-95, being mentioned in despatches and awarded the C. B. He had been P. M. O. in Calcutta and officiated as director-general I. M. S., 1901, and subsequently honorary surgeon to King Edward, 1905, and King George, 1910. From 1881 to 1892 he was superintendent-general of dispensaries and vaccination and civil and administrative medical officer, Rajpatana and the Punjab.

At Trinity College, Dublin, the vice-chancellor took the occasion of conferring degrees to tell of the splendid work of the alumni for both past and present. He said 650 members of the school are serving in the army medical corps, the Indian medical service, or in the Red Cross hospitals; 24 of them have been killed, 26 wounded, 10 are prisoners and 3 missing. They have been mentioned in dispatches 28 times. Five have military crosses, 3 the D. S. O., 2 the order of St. Michael and St. George, 3 the Bath. The Trinity College students with the colors number 1,500, of whom 707 have been awarded commissions. The total who have joined since the war broke out was 970. Of these 74 have been killed and 67 wounded. Military crosses have been conferred on 4.

5. Synchronous Inspiration and Systole in a Patient Exhibiting Equal Respiratory and Pulse Rates. G. D. White.

1. Problem of Classification and Segregation of Criminals.—E. R. Spaulding, the resident physician of the Reformatory for Women at Framingham, Massachusetts, believes that the problem of prison reform is one that the medical profession should help solve. She makes four general divisions of the offences for which 500 women have been arrested: 1. Alcoholism alone (21 per cent.). 2. Offences against chastity, with or without alcoholism; this includes all offences which have a probable sex basis, such as stubborn child, vagrancy, common nightwalker, keeping disorderly house, lewdness, fornication, adultery, etc. (58 per cent.). 3. Offences against property, such as larceny, breaking and entering, forgery, etc.; many of these cases also have offences belonging to the first two classes (15 per cent.). 4. All remaining cases, including offences against the person, such as abandoning children, assault, manslaughter, etc. These comprise but 6 per cent. The author then points out that if the criminal problem is one of treatment of the individual for his deficiencies rather than of punishment for the crime committed, the following fundamental provisions for the administration of such treatment are necessary: Adequate provision by the State for the permanent custodial care of all committable cases of mental defect whether or not they have a court record. The establishment of laboratories in our courts and correctional institutions for the study and diagnosis of all offenders. The equipment of all our institutions with facilities for classification and treatment of the various types which will remain even after the removal of the most defective. Such a classification will necessitate separate buildings, at least one of which should be equipped for hydrotherapy. The adoption of an indeterminate sentence, which shall enable us to treat patients until they are able to return with safety to the community. The physician has it in his power to do much toward educating the public to the need of fundamental measures of reform and toward counteracting the tendency toward superficiality of some enthusiastic believers in universal reform. His knowledge of mental and physical defect enables him to see more than the cross-section of the subject, which is represented by the population at present confined in our penal institutions, and to appreciate the social and economic waste, which is the result of our past neglect of generations of inefficients in the community.

2. Blood Pressure, Urinary Findings, and Differential Blood Counts in 662 Young Men.—R. I. Lee points out that there are few absolute standards for the normal in clinical medicine, and that physcians are better acquainted with disease and its variations than with health and its variations. The author then reports on the physical examination of the entire freshman class in Harvard University. Six hundred and sixty-two freshmen with the average age of 18 years, average height of 5 feet, 8 inches, and average weight without clothes, of 143 pounds, were each carefully examined once. He concludes that among young male adults in the usual condition of health a single determination of the systolic blood pressure frequently gives readings that are regarded as abnormal according to the usual standards. This deviation from the usual standard may be considerable and may be present on several occasions. In the absence of other abnormal findings moderate increase of systolic blood pressure seems to be of no significance. The diastolic blood pressure is much less subject to variation and is of considerable value in offering a control on an abnormal systolic pressure. Albuminuria was present in 5 per cent. of this group, and in only one case was there additional evidence of a true nephritis. Albuminuria in young male adults may be permanent, orthostatic or transitory, and is apparently of no serious significance. Glycosuria is unusual and in one case particularly, and apparently in another, was more than transitory and seemed associated with disturbed metabolism. The differential counts of the leucocytes of the blood in this group confirm our accepted standard for the normal.

3. Notes on Gastric and Duodenal Ulcers.—C. Graham states that, after reviewing his case histories from 1906 to 1915, he cannot find any pathognomonic symptoms or group of symptoms whereby he may reasonably locate peptic ulcer. It is not difficult to diagnose the presence of a peptic lesion, but it is quite difficult to determine whether the lesion is gastric or duodenal. Nevertheless there are some points that aid in their differentiation. In the whole picture, the coming and going of symptoms are not so distinctly seen in gastric ulcer. The pain in the gastric form often comes earlier after food (within 1 to 2 hours, in one-half the number), and frequently ceases in a short time, or before the next meal. It may return after a brief intermission, to be eased by the next meal, or the distress is such that food is refused lest pain be increased. This is more often the case in gastric than in duodenal ulcer, unless complications are present. When adhesions and perforations are present in any ulcerative lesion, and more so in those well above the pylorus, pain may begin sooner after food intake. This early pain is due apparently to peristaltic movements, tugging at the sensitive adhesions, quite as much or more so than to any acid fluid acting upon the chronic ulcer or open wound. Pain that comes immediately or soon after food intake seems to point to cardiac, fundic or other extensive ulcerations, perforations, adhesions, or obstructions. Coarse and large amounts of food may increase pain in any ulcer, but more constantly in gastric rather high in position, and high ulcers often seem to have periods of shorter duration (1 to 5 days) and shorter intermissions, or remissions which show a lighter grade of symptoms and tend to constant complaint. Duodenal or pyloric ulcers more often run an exact course day by day for days or weeks with decided food ease.

4. The Use of Calcium in Epilepsy.—J. Bryant states that in addition to faulty heredity, malnutrition seems with considerable frequency to precede the onset of epilepsy. Many poverty rations, such as white bread and potatoes, are very deficient in calcium. The author tried the effect of calcium in the treatment of epilepsy with gratifying results. He does not present calcium as a panacea. It may not cure any case, but it at least can be said that when added to existing only partly successful treatment by bromides, it has in some cases produced results sufficiently encouraging to make it seem desirable to mention its employment and possible value. The author desires to focus attention upon a broader question related to calcium metabolism. It has been held that such manifestations, as for instance chorea, migraine, tic, tetany, and epilepsy, are absolutely unrelated disease entities. Proof is lacking. It

is, on the other hand, not impossible that proof may be forthcoming to show that these diseases are, at least in some cases, merely different expressions of an underlying abnormality common to all. Three facts suggest that a lack of calcium may be such a common underlying factor in more than one of these conditions: many diets are deficient in calcium, calcium is deficient in the brain tissue of those afflicted with certain explosive manifestations, and some of these diseases have been markedly relieved by the adminstration of calcium.

2. Autolysin Treatment for Cancer.—C. Pope used autolysin in thirteen cases, during five or six weeks, and summarizes the results as follows: The injection, usually into the subcutaneous cellular tissue of the arm, is extremely painful for a period ranging from two to five minutes, and is followed by a dead, dull aching pain for approximately ten minutes. Reaction usually takes place within six hours and varies from malaise, depression, and chilly feelings to an actual chill, followed by a rise in temperature in no sense proportional to the chill. The first change usually noted by the author has been in the discharge. The first few injections may increase the quantity, but usually after the fourth or fifth injection there is a marked diminution and frequently a cessation. He observed that where he had to deal with an irritating mucopurulent, purulent, or sanguinopurulent discharge, this soon changed to semiclear or clear, thin, watery discharge, distinctly nonirritating in character and of small amount. Of all the changes that take place under autolysin, the cessation of the odor is the most remarkable. Pain is relieved and the appetite increased.

8. Weight Reduction.—R. H. Rose points out that for the intelligent supervision of weight reduction in cases of obesity, familiarity with the maintenance diet is a necessity. A maintenance diet is one sufficient to maintain the person's normal weight and strength. The author remarks that there is only one scientific method of procedure, and that is to prescribe the diet in detail as to amounts of each article, times of eating, etc. Exercise is an especially valuable adjunct to dietetic measures, and the more, the better. It increases the strength and the feeling of well being during the period in which the weight is being lost. Hard outdoor exercise, and very hard room exercises are of value. When the diet is low enough to cause weight reduction, the loss of weight will be over the most used muscles, and exercises can easily be devised to remove the weight where most desired. The author's purpose is to discuss the dietetic factors in weight reduction. His method in weight reduction is as follows: He asks the patient to tell him what he eats, not neglecting the very important inquiry as to amounts of oil, sugar, butter, bread, and dessert. It is important to elicit the amount of cream and butter used in the cooking—also amounts eaten between meals. Ice cream, it must be remembered, is quite nutritious. These facts are written in the history of the case, and he estimates at once the caloric value of the food the patient is accustomed to eat. He then revises his diet to make it equal two-thirds a maintenance diet for that individual when undergoing slight activity. A person weighing 150 pounds will lose one-quarter to one-half pound daily on two-thirds of a maintenance diet.

10. Backache.—S. Epstein considers some of the backaches of serious import caused by bone and joint lesions. The author points out that patients are not often examined with their underclothes removed, and their gait, posture, and spinal movements tested, that the tests for spasm of the psoas muscle and for the spasm of the posterior spinal muscle, which are just as important as abdominal rigidity in acute abdominal disease, are not fully appreciated by the general practioner, and that the general surgeon has removed appendices and ovaries and done laparotomies where the patient might have been much better served by a spinal support or plaster jacket.

18. Chloroform in the Treatment of Insolation. G. C. Hanson.

1. Gastric Cancer as a Sequel to Gastric Ulcer.—W. F. Cheney states that there is almost unanimous agreement that gastric cancer does originate as an ultimate sequel to chronic gastric ulcer. As regards the frequency with which this happens, however, there has always been disagreement among observers. One set of observers base their opinion on microscopic evidence of resected tissues; the other on clinical histories, course and outcome. The author is of the opinion that gastric cancer originates from gastric ulcer much more frequently than was formerly believed. Not every ulcer becomes cancer, but every ulcer is potentially cancer. It is impossible in early stages to distinguish those ulcers still benign from those becoming malignant. The author therefore concludes that surgery should be advised more frequently and more promptly than heretofore.

3. Stone in the Kidney and Ureter.—H. Cabot made a careful study of 157 cases at the Massachusetts General Hospital and comes to the conclusion that stone in the kidney too large to pass occurs most commonly between the ages of 10 and 40, and, with him, has come to operation most commonly between the ages of 20 and 50, which shows that the diagnosis of stone in the ureter is not made with great promptness. Renal colic is absent in a considerable proportion of the cases, and the pain caused by renal calculus may closely simulate that caused by various other abdominal lesions and is frequently mistaken for such lesions. The urine is persistently normal in a proportion of cases sufficiently large to make it an uncertain guide. The Roentgen ray is persistently negative in enough cases to make it dangerous to depend wholly on this evidence, but the com-

bination of unusual pain symptoms, a negative Roentgen ray and a persistently normal urine is fortunately rare.

9. Leucemia.—R. L. Wilbur states that the evidence thus far available points strongly to infection as the cause of the leucemias. It is probable that organisms usually of low virulence but of various kinds, perhaps working on a soil prepared by previous infections, can, when they secure a foothold in the bone marrow, spleen, or lymphatic glands, bring about the leucemic reaction alone or combined with disturbance of the red blood cell forming mechanism. Streptococci have been more frequently reported than other organisms in the blood and tissues of leucemic patients. The attempt to classify rigidly the leucemias and pseudoleucemias on purely morphological grounds is futile. A long series of bacteriological studies, including blood cultures and bone-marrow inoculations from living patients, will be required to settle the relationship of infection to the leucemias as well as the anemias. Foci of infection should be sought, and treatment directed against them. Only with the establishment of the cause can we hope for a sound therapeusis of this condition.

10. Abortion.—E. E. Montgomery writes that abortion may be the result of overexertion, infection or injury, but most frequently in first pregnancies through efforts to secure evacuation of the uterine contents by the administration of drugs or by mechanical measures. When the uterus is the seat of disease from previous infection or interruption of pregnancy, the pathogenic changes render the organ incapable of nourishing the incumbent until full term, and the contents are evacuated. When pregnancy recurs abortion becomes a habit. Frequently this is attributed to syphilis, which may be the cause, but it occurs more frequently independent of it.

12. Modification of the Abderhalden Test.—J. Bronfenbrenner, M. J. Schlesinger and W. T. Mitchell are inclined to think that the technic of the Abderhalden test is not very difficult. The difficulty in obtaining more constant results lies in the fact that the relations of the ingredients to each other are not properly understood. The authors come to the conclusion that the Abderhalden tests depend on the presence in the serum of specific substances which are not of a fermentive nature, that the substratum is not digested during the test, that dialyzable split products originate from the serum as a result of its autodigestion, and not from the substratum.

13. Pancreatic Ferment in Pulmonary Tuberculosis.—E. A. Gray and O. Pickman state that pancreatic secretions are seriously diminished by toxins of tuberculosis, in any stage. Rest, by reducing the production of toxins, aids in the return to a normal of these pancreatic secretions. Persistently low trypsin readings are prognostically bad. Low amylopsin values are of lesser prognostic importance. All interpretations must be made with due consideration for anorexia, overeating and diarrhea.

14. Loan Collection and Photomicrographs in the Teaching of Pathology.—E. Scott and J. Forman write that the use of the loan collection and photomicrographs in the teaching of pathological histology possesses the following advantages: It compels the student to write concise and accurate descriptions of the specific cellular elements and of the lesions which they build up. It allows the discussion or quiz to be followed in detail with much greater ease. It gives time for the introduction of more experimental demonstrations. It permits of closer correlation between the gross and the histological pathology. It enhances the value of the notebook. Most important of all, it opens a greater opportunity for the student of medicine to do some thinking for himself.

16. Unusual Type of Cardiac Arrhythmia.—P. D. White records an instance of gross cardiac arrhythmia due not to auricular fibrillation or sinus arrhythmia, but to ectopic ventricular contractions.

17. Trichinosis Simulating Frontal Sinusitis.—E. L. Pratt reports three cases of trichinosis simulating frontal sinusitis and states that the diagnosis in all three cases rested on edema of the lids with absence of edema elsewhere; negative nasal findings referable to the accessory sinuses; the history and the eosinophilia. In all three cases pain in the region of the eye and frontal sinus was noted.

18. Chloroform in Insolation.—G. C. Hanson administered chloroform cautiously by inhalation in three cases of unconsciousness from insolation and in all three cases rapid improvement occurred.

4. Recrudescence of Sepsis in Healed Wounds.—R. J. Bond calls attention to a renewed septic process in completely healed wounds—no mere slight reaction, or swelling or effusion, which subsides with rest and time, but a violent reaction on the part of the tissues against a renewed virulent infection that ends in local suppuration, and that in some cases is sufficiently serious to threaten the limb or even the life of the patient. He points out the necessity of knowing more about the life-histories of pathogenic organisms in their relation to the body tissues, which are now obscure. For instance, we should know more about the conditions under which pyogenic organisms can dig themselves into the tissues and remain quiescent in sheltered situations without causing any local or general symptoms and without losing their virulence, just as the malaria organism is supposed to bury itself in the bone marrow or the tubercle bacillus to become encapsulated in a lymph gland. To what extent is the capacity of such organisms to remain alive and virulent the result of the formation of the barrier of fibrous or granulation tissue which surrounds them, or is it aided by the concomitant presence of a foreign body or some devitalized piece of tissue—for example, a fragment of bone—within the uneven surfaces of which the cocci can more readily defend themselves against phagocytic action? Is the time interval of essential importance, and, if so, how long after the complete healing of a wound under ordinary conditions may we suppose that the cocci or bacteria which caused the original sepsis can retain their virulence and their capacity for renewed activity? These are some of the questions that came to the author in his experience with cases of the reappearance of sepsis in completely healed wounds.

5. Trench Nephritis.—N. Raw gives a record of five cases and concludes: 1. There seems to be some association between life and conditions in the trenches and the disease. 2. None of these patients had any previous kidney trouble, and they all made a good recovery from what seemed to be a serious lesion of the kidney structure. 3. Bacteriological examinations were negative, and one is inclined to think that some infective process—giving rise to a toxin with a selective action on the renal epithelium—is the cause of this unusual symptom complex.

7. Rotatory Nystagmus Overcome by Optical Treatment.—T. S. Barrie reports a case of concomitant rotary nystagmus in a girl seven years old, alleged to have existed since birth, which disappeared after wearing glasses that corrected the errors of refraction. The author states that the interest of this case is the disappearance of the nystagmus under optical treatment, for according to May and Worth, "infantile cases (of nystagmus) are not amenable to treatment, though the condition sometimes becomes less marked with advancing years; the correction of high errors of refraction seldom improves vision."

1. Experiences in the Treatment of Typhoid Fever by Stock Typhoid Vaccine. — H. W. Wiltshire and A. R. N. MacGillycuddy report their experience in the treatment of fifty cases of typhoid fever by means of the stock therapeutic typhoid vaccine supplied from the Royal Army Medical College. Very few of their patients were admitted to hospital in the early stages of the disease. The general result of treating these fifty cases has been to convince the authors of the value of vaccine treatment to such an extent that they should now regard the withholding of vaccine from a suitable case in the early stages as an unjustifiable experiment. They have had no experience of living vaccines, and practically none with autogenous vaccine. The results obtained, and the power and limitations of vaccine which they have found in clinical work, are only such as theoretical considerations should lead them to expect. In the earlier stages its use as a direct antagonistic to the pure typhoid infection is obvious. At the same time it may be regarded as a powerful prophylactic agent against secondary infections. The latter find their opportunity in the lowered resistance of the body caused by the typhoid toxemia. The vaccine, by diminishing or completely ending this toxemia, may prevent the opportunity for the occurrence of secondary infection altogether. Once secondary infection has taken place, a dual toxemia has to be fought, and it is not to be expected that a vaccine specific for one organism can neutralize both. It can still help by tending to neutralize its own antagonist —the primary infection—but in this there is a risk, as they found in some cases, that the reactionary period may be favorable for an extension of the secondary infection. Hence in these cases a marked reaction must be avoided by care in dosage, and, when possible, a specific antagonistic must be provided to fight the secondary infection. This view is strongly supported by the good results obtained in some recent cases by the use of typhoid vaccine and pneumococcus vaccine combined. Their conclusions are as follows: 1. Stock typhoid vaccine is a valuable therapeutic agent for the treatment of typhoid fever. 2. The treatment should be started as early as possible with an initial dose of 250,000,000. 3. A reasonable suspicion that a patient is suffering from typhoid fever is sufficient indication for commencing vaccine treatment. 4. The treatment is quite harmless to patients who may subsequently be proved not to be suffering from typhoid fever. 5. An interval of three days should be given between doses. Shorter intervals are not well tolerated. When a longer interval is given, if four days the dose should not be increased, if over four days the dose should be reduced. 6. Great care must be used in dosage if secondary infections of the lung are present. If possible, the typhoid vaccine should be combined with a vaccine suitable for the secondary infection. 7. Doses should be continued for ten days after the temperature is normal as a preventive against relapse. 8. Preventive inoculation exerts slight, if any, influence on subsequent vaccine treatment.

4. Neurasthenia Gastrica.—J. C. McClure was encouraged to revive an old title by the fact that he has encountered in considerable number a type of neurasthenia associated very definitely with gastric and intestinal symptoms. His paper is based on the continuous observation of 100 cases during the past four years. He examined the gastric contents in 20 of these cases, all of whom suffered from pain and discomfort in the epigastrium, beginning two or three hours after food and relieved by eating. In 16 out of the 20 the total acidity was increased; in 2 the total acidity and hydrochloric acid content were normal, while in the 2 remaining cases the total acidity was less than normal and hydrochloric acid practically absent. In the 16 cases in which the total acidity was increased the proportion of hydrochloric acid varied enormously. In 3 cases there was definite hyperchlorhydria, but in the remaining 13 cases the hydrochloric acid was either normal or definitely diminished. In all those cases where the total acidity was high without hyperchlorhydria, the high acidity was due to the presence of organic acids—namely, butyric acid and acetic acid; in no case was lactic acid present. Large quantities of mucus were usually present in the stomach washings, and sarcinæ were found in three cases. The train of symptoms associated with neurasthenia gastrica is curiously constant. Patients complain of being easily tired, both physically and mentally. Inability to concentrate attention on work which was at one time easy for them is a frequent trouble. Memory tends to become capricious. Headaches, either of a dull, heavy kind with a frontal distribution and worse in the morning, or sudden bouts of migraine-like disturbance, are very common. A certain uneasiness in the left hypochondriac region, occurring at varying times after food and in the evening, either with or without a feeling of distension in the left hypochondrium and epigastrium, is a very usual experience. At times the gastric symptoms are obtrusive, so that a patient may complain of frequent attacks of nausea and almost constant burning in the region of the stomach, especially one to three hours after food, while flatulence may become so great as to be a social nuisance. It is not uncommon for the patient to suffer from a sensation of obstruction on an attempt to swallow food, especially at the beginning of a meal, and this sensation of obstruction is often associated with a feeling of constriction in the chest and a dragging sensation in the neck. Sometimes it is also accompanied by profuse salivation. Constipation is the rule, but is not invariable. Cardiac symptoms are very common. Attacks of palpitation often occur, produced sometimes by exercise, especially immediately after food, but more often coming on without any apparent cause, while the patient may be resting quietly. Insomnia of a peculiar character is common. In those who go to bed early, sleep comes quickly but about 2 o'clock in the morning they become wakeful. Those who go to bed late cannot get to sleep

until about six o'clock in the morning. Dilatation of the stomach, signs of intestinal stasis, and exaggerated tendon reflexes are commonly found. The author points out that an essential part of the treatment is the removal of any source of irritation or toxemia apart from the stomach itself. The teeth, gums, appendix, and colon should be kept in mind in this connection. Rest and diet are not successful unless they please the patient. The author advises against "overfeeding" and insists that the stomach should be permitted to empty itself before taking another meal. Having removed all other sources of toxemia and irritation, the treatment of the gastric condition by the method described by Dr. Percy Mitchell should be instituted. Without going into unnecessary details it may be well to give a short description of the manipulation necessary for this form of treatment. The patient lies on his back in bed or on a couch; the physician sits on his right side facing the head and places the phonendoscope over the pyloric region of the stomach. He then with the fingers of his right hand strokes the skin very lightly just inside the cartilages from the tenth to the seventh ribs on the left side of the patient. The stroking should be intermittent and a slight vibratory character given to the movement. The skin is stimulated in this way until a contraction of the stomach is educed, this contraction being expressed by a succession of explosive or gurgling sounds audible through the phonendoscope, due, presumably, to the passage of gas or fluid through the pylorus. The moment that a contraction of the stomach takes place stimulation of the skin should be intermitted until the gurgling and explosive sounds have entirely ceased. The process is then repeated until another contraction takes place, when another pause is made until all sounds cease. Treatment in this way is carried on for some 20 to 30 minutes at a time, at the end of which it is usually found that the size of the stomach is considerably reduced. It is not possible in most cases to empty the stomach completely at the first sitting, nor is it particularly desirable to do so. It is only after treatment has been carried on regularly on successive days for upward of a week that frequent and powerful contractions are educed and the size of the stomach brought to limits approaching the normal. In many cases a contraction is not educed very easily by stimulating the skin in the area already described, and it is necessary to stroke the skin overlying the lower costal cartilages from below upward with a sweeping and slightly interrupted movement, from about the tenth costal cartilage almost to the left edge of the sternum, following more or less the line of the normal upper border of the stomach as ascertained by auscultatory percussion. By stimulating the two areas alternately a contraction may often be educed where stimulation in only one area has failed.

7. Case of Syphilitic Nephritis Treated by Salvarsan.—N. MacDonald reports a case which is very typical of early syphilitic nephritis in its clinical course. It is no longer open to question that syphilis in its early as well as in its later stages may give rise to nephritis, and, indeed, the dependence of one upon the other is probably more common than is generally appreciated. The nephritis in this case manifested itself about the fifth month after infection, which appears to be about the usual period, though it may be later or may be much earlier. In one reported case it occurred before the secondary roseola. The onset was insidious and without marked symptoms or derangement of health. The percentage of albumin in the urine tended to be very high, and the albumin came down on warming the urine long before the boiling point was reached, forming a voluminous and peculiarly white deposit even when the urine was high-colored. There was a great tendency to rapid and extensive dropsical effusion which cleared up with unusual rapidity. In this case, as in others reported, there was also pleural effusion. Throughout the case the patient's feeling of good health was quite out of proportion to the gravity of his symptoms. Even with extensive dropsy and great albuminuria he always averred he felt quite well, and he had none of the symptoms usually met with in nephritis from other causes. The blood pressure was not much raised except on one occasion, and though there is not sufficient evidence of the effects of blood pressure in syphilitic nephritis, in this case, as in others the tension was not much raised. In late syphilitic nephritis the blood pressure may be very high with extensive arterial degeneration. The treatment by salvarsan was adopted after due consideration, notwithstanding that albuminuria is said to increase the dangers of its administration, as mercurial and iodide treatment had failed. In several cases treated, salvarsan has not produced untoward effects when albumin was present. It was given with great care in small doses and so far has resulted in the disappearance of the Wassermann reaction.

Berliner klinische Wochenschrift.

August 30, 1915.

Clinical and Therapeutic Experience with Tetanus.—Pribram's serial article on this subject is summed up by its author in part as follows: Extreme variation in type makes all generalization difficult, so that means should be found to individualize cases. Those with trismus, episthotonus and convulsions of peripheral muscles have a relatively fair prognosis *per se*, but pulmonary and cardiac complications may cause death. Cases with spasms of the diaphragm and glottis have an unfavorable prognosis, because these manifestations cannot be reached by treatment; epigastric pain points to forthcoming spasms of the diaphragm. In very rare cases tetany has been confounded with true tetanus. Next to death from spasm of the glottis, confluent lobular pneumonia is the chief cause of mortality in tetanus. This affection may be shown in time to be an integral part of the disease. Spasm of the diaphragm, by compressing the large veins, causes hemorrhages and stasis in the viscera. The victim of tetanus—both as a disease and as a cause of death—usually presents the status thymico lymphaticus, which must serve as a predisposition. Prophylactic injections against shell wounds alone are good as far as they go but tetanus may develop from very slight injuries, mere chaps. Ether anesthesia should never be used in tetanus lest it provoke spasm of the glottis. The problem of treatment for future consideration is how to combat the tonic spasms of the diaphragm and glottis, for magnesia and chloral fail here completely. In theory the course is plain: Tracheotomy and bilateral phrenicotomy should be performed and morphine given in massive doses to restore normal breathing. This can do no harm if artificial respiration and oxygen are immediately available to offset overaction. Magnesium may be given by the intradural route as a sedative to contraction of the voluntary muscles.

Dysentery Bacilli of the Toxin-Poor Type.—Arnheim says of these organisms that they demand better cultural conditions, for only in a certain per cent. are cultures positive. The diagnostic possibilities of the dysentery-Widal reaction are to be regarded as slight. The carrier problem, as it relates to this organism, is not a serious one in comparison with the exciters of other infectious diseases. The Y type so-called of dysentery bacillus is identical with *B. flexneri*. In individual cases dysentery bacilli appear in the urine,

although they are never found in the blood. Attempts to locate dysentery bacilli in the ordinary articles of diet were fruitless. The author's experience with dysentery during the present war has been almost wholly with cases caused by the so-called toxin-poor bacillus (Y bacillus, *B. flexneri*). In but two cases did he find the virulent, Shiga-Kruse organism.

Gunshot Wounds of the Lung and Tuberculosis.—In the course of an article by Korach on the diagnosis and treatment of gunshot wounds of the lung, the author states that the relationship between these injuries and tuberculosis is problematical. Many young recruits in the haste of mobilization doubtless pass the examiners with slight foci of tubercle in the lungs. Hence whenever a case of pulmonary wound is received in a hospital the sputum should at once be examined, and the apices carefully examined. In this way antecedent lesions may be excluded; so that when tuberculosis develops some time after the traumatism it may be regarded as traumatic phthisis.

Münchener medizinische Wochenschrift.

August 24, 1915.

Circulatory Disturbances Due to Shock Toxins.—Mautner and Pick have studied the phenomenon of lowered blood pressure with which shock is ushered in On the supposition that a toxic principle is responsible they have injected certain substances into the circulation with and without previous sensitization. Among these are pepton and β-imidoazolethylamin, albumoses, bacterial vaccines. The original teaching has been that shock poisons are vasodilators which lower the blood-pressure of the abdominal vessels. The authors' researches have led them to the opposite conclusion that the toxic substances are powerful vasoconstrictors; *i.e.* they produce intense contractions in certain areas which result in anemia. Three vascular capillary areas are attacked in this manner; viz.: the intestines, liver and lungs. Histamin, pepton and the anaphylaxis toxin bring the intestinal vessels to contraction, with resulting increase of blood pressure in the greater circulation. But when the capillaries of the liver and pulmonary circulation contract, the left heart and general circulation tend to become empty and there sets in a sudden fall of blood pressure. These pure conditions, affecting separately the two circulations, give extreme pictures; but between the two we may see every gradation, in which one or the other system predominates, or resets unevenly. That the blood pressure is lowered in shock appears to be due to the greater sensitiveness of the pulmonary circulation to shock toxins.

Acute Yellow Atrophy of the Liver in Syphilis.—Bendig reports a case of this incidence in a woman in the ninth month of gestation. As she had also received injections of salvarsan, no less than three separate causal factors were to be considered—syphilis, pregnancy, toxemia and salvarsan, since each of these has alone been accused of causing the lesion. The author is perhaps unaware of the belief of many pathologists that pregnancy is the essential and not incidental cause of an acute hepatitis followed by yellow atrophy. The syphilis toxin is by common consent regarded as a not infrequent cause of this lesion. Salvarsan, if able to produce the latter would in all likelihood act as an arsenical compound. In the hepatic atrophy which follows poisoning by phosphorus or arsenic, the organ is usually actually larger than normal from fatty infiltration. The case ended fatally. The woman was young and strong and as she was near term when infected she received an intensive Hg-salvarsan cure. In six weeks from admission date she began to complain of epigastric distress and dyspnea and showed great restlessness. The liver then appeared to be enlarged. Next day jaundice appeared and death occurred suddenly. Autopsy revealed extensive internal hemorrhages and universal jaundice. The disease had practically been manifest but forty-eight hours, and the terminal symptoms were those of acute cholemia (great unrest, mental confusion, convulsions with hypostatic pneumonia). At autopsy the liver was found to be smaller than normal with all evidences of acute yellow atrophy. The author had seen a case very similar to the preceding but the young woman, a recent syphilitic, was not pregnant nor had she been treated with salvarsan. It is by no means unlikely that the cases on record as acute yellow atrophy following salvarsan injections, were due purely to syphilis. The first patient having also been treated intensively with mercurial inunctions, the author, believing acute yellow atrophy to be due to toxins, is inclined to think that the combination of syphilis, pregnancy, salvarsan, and mercury could have determined a condition which might not have developed had either one been absent.

Serotherapy of Scarlet Fever.—Reiss and Hertz report results at the Frankfurt Medical Clinic with several sera in the treatment of scarlet fever. These measures no longer come under the head of experiment, because they have now been fully incorporated in practice. While convalescent serum represents the ideal, this is not always forthcoming and must then be replaced by normal serum. Specific sera are sometimes exhibited. The number of patients who have been treated with convalescent serum is 27, naturally of severe type. All but 3 recovered. Characteristic was the complete transportation of symptoms upon infusion of serum. Patients out of their heads, delirious, would be found 12 hours later reading books. The three patients who succumbed did excellently under the serum, but one died of bronchopneumonia and in a second case the cause of death preexisted before the disease developed. The third case was a fulminant one and death could not be stayed. The doses of serum were large (50 to 100 c.c.) and given repeatedly. But 4 patients received normal serum, which has a similar action, but not as marked. Only 2 patients received an antiserum and with good results. Normal horse serum exerts no action whatever on the course of scarlet fever. The serum treatment of the latter is indicated only in severest cases as identified by small, irregular pulse, cyanosis, and bad mental state; it is contraindicated whenever the severity of the disease is due to complications, over which it can have no direct control. It can render signal service only in the first 4 or 5 days of the disease. The technique is very elaborate, and the treatment could hardly be carried out in the absence of special facilities.

Origin of the Hard, Traumatic Edema of the Back of the Hand.—Stromeyer refers to the original recognition of this condition about 1901. Since that period some twenty papers have been devoted to it. The author reports a personal case as follows: Patient was a strong country woman of 30. While cleaning a needle she had pricked the back of her hand. When seen a few days later the wound was barely visible in the second interosseous space of the left hand, ½ cm. from the knuckle. An *x*-ray picture showed a piece of sewing needle in the hand, 2 cm. long, containing the eye. The object was readily removed and the wound healed

kindly. Some pain persisted on motion, and the dorsum soon began to swell. This progressed in all directions but spared the ball of the thumb. The swelling also stopped short at the wrist and fingers and the color surface remained unaffected. The operation scar was extremely sensitive. The *x*-ray find was negative. The hand was first kept at rest for a number of days, at the end of which massage and hot air treatment was begun. Slight improvement after massage was quickly followed by return of former hardness. At last after 3 months of non-improvement the author excised the scar, which had become a source of torment to the patient. The result was surprising as in a few days the hand edema began to disappear, the fingers became movable, and within 6 weeks after excision the hand became quite normal.

Deposits of Coal Dust in the Intestine. — Lubarsch states that a deposit of coal dust is often found in Peyer's patches at the lowest segment of the small intestine. Of 81 subjects 11 were children between the ages of 2½ and 16. The dust is swallowed, after having been inspired and is then taken up by the intestinal villi. This ingestion anthracosis has no necessary connection with anthracosis of the lungs and intrathoracic lymph nodes and is probably not affiliated with anthracosis of the retroperitoneal lymph nodes. There is quite a parallel, as regards separate involvement of digestive and respiratory, between anthracosis and tuberculosis.

Posttyphoid Paralysis.—Zadek states that peripheral palsies are not rare after typhoid. Actual neuritis is not so common. Most of these palsies are mixed—sensori-motor. Pure motor palsies sometimes occur, and bear a striking resemblance to post diphtheritic paralyses. There is no connection between any of these nervous phenomena and myodegeneration. The prognosis is good and varies inversely in this respect with the severity. Peroneal paralysis is common in all palsies of toxi-infectious origin. Either the whole or part of the nerve distribution may be involved. True central paralyses are far more infrequent than peripheral forms. Taking no account of cases due to meningitis, the usual form is hemplegia, the causes being cerebral apoplexy or thrombosis. The nature of this phenomenon is obscure, especially when it occurs during convalescence. The author relates a personal case of cerebral apoplexy which occurred in a child during convalscence from typhoid. Recovery took place so that the mechanism can only be surmised. Conditions which obtain in apoplexy of advanced years do not of course apply in this case. Here hemplegia set in rapidly, no contractures developed, there was a positive Babinski and no involvement of cranial nerves. Such a case comes under so-called functional apoplexies of which uremic hemplegia is a variety.

Ovariotomy in Pregnancy.—Unterberger, Jr., reports 8 cases of this intervention, in one of which the operation was bilateral, while another was a parovarial cyst in which the adnexa were left behind. In the two last named cases abortion followed the operation, gestation being but slightly advanced (one and two periods missed). Many cases are on record in which double ovariotomy in very early pregnancy did not interrupt the latter, but in the majority abortion has been the rule. It is not apparent why extirpation of a parovarian cyst could cause abortion. The author in these aborting cases is inclined to accuse the internal secretions, but does not venture an explanation of the modus operandi.

Treatment of Abdominal Injuries in the Field.—Von Brunn differentiates entirely in this matter between active and stationary warfare. With troops in motion he never interferes save when the bowels protrude. Not only do these cases do fairly well when let alone but all the surgeons' time must be devoted to the men on the firing line. With troops who fight while stationary, he does not operate on any kind of wounds in the upper abdomen, but any other portion of the belly he attacks at once whenever he can strike a balance after deliberation as to what should be done. The decision must be made without too much delay, and the abdominal cavity must always be thoroughly irrigated with saline infusion.

Deutsche medizinische Wochenschrift.

September 2, 1915.

On the Conjectural Exciting Cause of Typhus.—Arnheim ignores entirely the discoveries of Plotz and Proescher, so that his paper may have been written before the latter were published. He deals chiefly with the finds of von Prowazek, Rabinowitch and Petruschky, and the results of his personal labors. He has isolated and cultivated a bacillus which closely resembled Petruschky's, but presents certain differences. As a matter of fact the author's finds were by no means uniform, and it was impossible to state whether the different strains produced by culture were really identical. Bacilli were cultivated from the blood, sputum and urine of many typhus cases. Protozoa may straightway be excluded as causes. The finds of the author will doubtless soon be contrasted with those of Plotz and Proescher; until this shall have been done the elaborate work of Arnheim can count for little, for both of the others have reached a more advanced stage of investigation, while Proescher's discovery is a diplococcus.

An Attempt at a Specific Treatment of Trachoma.—Loewenstein and Herrman report that the former has been at work on this subject for ten years. Only the crude disease product could be used for the production of antigens. Cases were selected which presented trachoma granules. These were then expressed, the instrument cleansed and the granules rubbed up in a mortar with saline infusion and then injected without further elaboration beneath the skin. No reaction of any sort followed, including allergy. Some 8 or 10 days after injection the disease began to improve and in three weeks more the lesions had cicatrized. In certain cases trachomatous pannus when present disappeared and the cornea cleared up. The return of vision was remarkable.

External Treatment of Chronic Rheumatic Affections.—Schattauer mentions first the old empirical and household remedies used externally in chronic rheumatism. These all belong under rubefacients, among them being opodeldoc and oil of mustard. The physician added to these cantharides and iodine. The ethereal oils were also much used for this purpose and oils of juniper and turpentine, camphor, and menthol. Next came a period in which salicylic acid and its derivatives under various forms were applied locally. With protracted employment, however, the members of this group proved to be local irritants. A new synthetic has recently been devised with the aim of doing away with this irritation. The molecule contains salicylic acid and trichlorobutyric alcohol, to the latter of which it owes analgesic properties. This substance (marketed of course under a proprietary name) has been used extensively among the troops during the present war.

Insurance Medicine.

Policyholders as a Medium for Increasing Longevity.—Dr. W. P. Blackford, medical director Commonwealth Life Insurance Company, Louisville, Ky., read a paper with this title before the fifth mid-year meeting of the Medical Section of the American Life Convention. He said that the movement of life extension had only recently taken a definite form, but for years it had had the support of the medical profession as a whole and much good had been accomplished by its untiring efforts and it was deserving of much credit for arousing the interest of laymen and business organizations to the consideration it was to-day receiving.

By the very nature of their work, and the mutual dependence of the different companies and their various policyholders, life insurance companies in connection with their agency forces and more especially their corps of medical examiners, were in a better position than any other organization for increasing longevity through the medium of their policyholders. It was a long step in this direction when, in 1909, forty-three of the large insurance companies in this country and in Canada, with a volume of statistics in no other manner available, opened their books of experience for the benefit of mankind. Never in our history has preventive medicine received such a support, and when we consider how large a percentage of our untimely mortalities is due to preventable diseases, which are costing our nation untold misery, affecting not only the present but future generations, and costing our insurance companies millions of dollars, filling our penal and charitable institutions, we are surprised that the movement did not have an earlier origin. The millions of dollars that were spent annually for charitable purposes proved that the hearts of our people were touched by the condition of our fellowman, and yet the millions spent were only palliative, allaying only the pain and suffering of the individual and did not protect those that might become infected through contact or the innocent offspring who might inherit some hereditary taint or predisposition. If millions were so generously given for palliation what should be given and what might we expect, if our lay people only realized the difference in value of relieving a condition in an individual and the prevention of a multitude of the same condition.

He believed the day was dawning when our people would demand the truth and every disease would be controlled in a businesslike manner. There was certainly no business or scientific reason why syphilis, a disease which had claimed thousands of years of mankind by early mortality and one which was absolutely preventable, should not be eradicated. He was aware of the unsatisfactory results of the various methods that had been tried, such as inspection, segregation, etc., but he believed the added information of the past few years regarding this disease placed it in a different light from that in which it had been formerly regarded.

To a certain extent, those who appreciated this condition and its significance took sufficient precaution against infecting others, but those who were less careful should be punished. With a registration board, State or national, could be filed the records as to date of infection, length of treatment, etc., and those individuals should not be granted a marriage license who had not had a two years' treatment from the initial infection. Some plan with such an object in view should have the support of every reputable physician and intelligent citizen, and he saw no reason why the policyholders and people at large, who had reached the age of maturity, should not be enlightened for self-protection and as an assistance to the State along this line.

The crusade against tuberculosis and most of the infectious diseases that had been waged for the past several years was being felt, and but for this, apparently, our mortality rate for the past ten years would have shown an appreciable increase. Some talks were given which showed that the spreading of childhood diseases was being prevented by the regulations of municipal and State authorities. The older citizens ignored municipal regulations, consumed too much alcohol, meats, and other nitrogenous foods, and did many things that tended to impair the circulatory and other systems of the body; hence, the consideration of the advisability of periodical medical examinations of the policyholders with the view of detecting the degenerative diseases in their incipiency and through counsel assist them to longer life. The Company co-operated in over 140 cities by the distribution of literature and by urging policyholders to enter into clean-up campaigns.

He did not wish to be understood as recommending that insurance companies enter into the movement purely from a commercial standpoint, expecting money spent to be promptly replaced by the saving in mortality, yet we might reasonably hope for results in that direction if the movement became sufficiently universal.

In the consideration of conservation of the nation's available resources the most important was to be found in the life and good health of the individual members; and the loss of human energy through mortality by preventable diseases constituted the greatest waste of our resources to-day. It was also true that this waste of human energy was the result of ignorance or neglect of prophylactic or curative measures well known to science.

With the health of the nation as its greatest asset our insurance companies had an interest in the good health and favorable mortality of the people, and might we not hope to see a cooperative movement of these organizations that would be for the betterment of our nation?

Warranty Against Disease—Effect of Examination by Company's Medical Examiner.—An insurance policy contained the warranty that, "This policy is void if the insured * * * has had before its date any pulmonary disease." In an action on the policy the evidence showed that the insurance company had a medical examination made of the applicant before the policy was issued, and the applicant's family physician testified that the applicant had pulmonary disease prior to the date of the examination. It was held that the express provision of the policy was binding and would be enforced, although the company's medical examiner failed to discover the presence of the disease.—Hanmore v. Metropolitan Life Insurance, La. Supreme Court, 68 So., 385.

What Constitutes Loss of the Hand.—A policy providing compensation for accidental loss of a hand by removal at or above the wrist is held in the Oregon case of Moore v. Ætna L. Ins. Co. L.R.A.1915D, 264, to cover an accident requiring the removal of all the bones of the fingers, leaving only flesh enough to protect the bones remaining and the thumb in a stiffened and useless condition.

Book Reviews.

MICROBES AND MEN; A SURGEON'S PHILOSOPHY; DOCTORS VERSUS FOLKS. TO-MORROW'S TOPICS SERIES. By ROBERT T. MORRIS, M.D. Illustrated. Three volumes; $2.00 each. New York: Doubleday, Page & Co., 1915.

WHEN an author says in the preface that in reading his book "one may open the pages at almost any point and find something to which he will object" the effect is at least to rouse the reader's interest. And when a little farther on the eye lights on the phrase, "When men smile and agree, progress weeps," he proceeds with the perusal in pleasant anticipation of intellectual conflict. In fact, most readers *will* be likely to disagree with much that is to be found in these three delightful volumes, but they will also be charmed and even fascinated. The books form a triology of universal scope, a true *Weltanschauung*, for there is little in the heavens, the earth, or the waters under the earth that is not discussed at ample length.

The first volume of the series "Microbes and Men" gives the keynote to the others, for the microbe, omnipresent and omnipotent, is the mighty protagonist of the whole world drama as it reveals itself to the author's scrutiny. All of life and all of man's activities—literature, science, philosophy and art, the feminist movement, the wars of nations, the problems of education and of science, social questions and the declining birth rate—all are phenomena dependent in the last analysis on the microbe and the reactions produced by it in more highly developed forms of life. The optimism of Stevenson is fostered by the toxin of Koch's bacillus, and the gloom of Nietzsche by the depressant action of the colon group, while Shelley's alternations of ecstasy and *Weltschmerz* depend on a fluctuating mixture of these two antagonistic influences. The state of the large intestine is of profound importance in regulating its owner's mental and physical activities, and toxemia originating there may have the most far-reaching and unsuspected consequences not only to the individual but to the cosmos. In short "A man is what his bacteria make of him," and no doubt the author would say that Pope should have written, "The proper study of mankind is Bacteriology," instead of the familiar phrase.

The second volume deals with matters of equal import—religious belief, the soul, work and play, conjugal infelicity, and the relation of the sexes (including a discussion of the double standard from the physiological standpoint), insanity, sleep and the beliefs of the Freudians, etc. Wholesome advice is offered to young men suffering from the "love psychosis," as for example, that an *x*-ray picture of his intended's enteron would be of much more use to a lover in estimating the chances of future compatibility than a photograph of her face. The author's views of life and its problems, while based on the knowledge of the scientist and medical man, are always kindly, cheerful, and wholesome, constructive and not destructive, and form a philosophy which is replete with the joy of work and of play, and full of interest in the big and little things of daily life. Most readers will probably wish, however, that he had expressed a little more clearly his conception of "Nature," a mysterious *deus ex machina* to which he constantly refers without precise elucidation, but which he appears to regard as the prime mover of all things, as for example, when he says "Nature placed the idea of a personal God in the mind of man as a working library of herself in a compact edition."

In the third member of the series, "Doctors versus Folks," Dr. Morris addresses himself especially to his younger colleagues. There is much of autobiography in the volume, and many diverting anecdotes of experiences, pleasing or the reverse. He also discusses some of his own original work in medicine and surgery, and in various of his hobbies, especially in horticulture. The books bear evidence of an astonishing versatility in intellectual pursuits and attainments, and of a mind of extraordinary originality and freshness of outlook. There is something here for every reader and every mood, from grave to gay, and the volumes once begun can be laid down only with reluctance.

MOTHERCRAFT. By SARAH COMSTOCK. Illustrated. Price, $1.00 net. New York: Hearst's International Library Co., 1915.

THIS book comprises a series of articles that first appeared in *Good Housekeeping Magazine* and that present in simple language the elements of the care of pregnant woman, and of the care of the infant and growing child. The chapter headings are as follows: Motherhood To-morrow; The Days Before the Stork; Hygiene in the Baby's Wardrobe; Feathering the Nursery Nest; Feeding the New Baby; The Growing Body of Your Child; A Footing for Life, and The Growing Mind of Your Growing Child.

WHAT EVERY MOTHER SHOULD KNOW ABOUT HER INFANTS AND YOUNG CHILDREN. By CHARLES GILMORE KERLEY, M.D., Professor of Diseases of Children, N. Y. Polyclinic Medical School and Hospital. Price 35 cents net. New York: Paul B. Hoeber, 1915.

THIS is a flexibly bound pamphlet of 54 pages of text with a similar number of blank pages for notes. It provides easily understood and practical instructions regarding the care of infants and young children for the mother of moderate means.

X-RAYS, HOW TO PRODUCE AND INTERPRET THEM. By HAROLD MOWAT, M.D. Edin., Temporary Lieutenant, R.A.M.C.; at present Officer to X-Ray Department Meerut Indian General Hospital; Radiographer to Metropolitan Hospital and Royal Chest Hospital. Price, $3.00. London: Henry Frowde, Oxford University Press; Hodder & Stoughton; New York: Oxford University Press, 1915.

THIS book presents an account of the *x*-rays for the benefit of those who have little or no knowledge of the subject. Part I deals with the production of the *x*-rays and comprises chapters on the *x*-ray tube; sources of supply, etc.; accessories; localization of foreign bodies; and technique of examination and development. Part II includes chapters on the thorax, the digestive tract, the urinary system, bones and joints (injuries), and bones and joints (diseases). There are 106 excellent illustrations, including drawings of apparatus and reproductions of *x*-ray photographs. The latter represent all the important clinical conditions in which the *x*-rays are of diagnostic value. The therapeutic applications of this agent are not considered in this volume. The author has acquitted his task admirably, in writing a succinct and clear account of the *x*-rays. The Oxford University Press has in this instance maintained its high standard of workmanship. The volume is printed in large type on heavy paper and is well bound.

LOSS OF HAIR. Baldness, Falling Hair, Prematurely Gray Hair, and Seborrhea Successfully Treated by the new Quartz Light Rays. Authorized Translation from the German of Dr. FRANZ NAGELSCHMIDT by RICHARD W. MULLER, M.D. Price, $1.50. New York: William R. Jenkins Company, 1915.

THIS book sets forth the results obtained in the treatment of 200 cases of alopecia areota, alopecia, seborrhoica, and premature and senile alopecia by means of the modified Heraeus-Quartz lamp, whose efficacy depends upon the ultraviolet rays. The case histories are all briefly recorded, following which there is a description of the apparatus used and of the technique of its application.

DIET AND DISEASE IN INFANCY. By HECTOR CHARLES CAMERON, M.D., F.R.C.P.; Assistant Physician in charge of the Department for Diseases of Children, Guy's Hospital. With four colored plates and thirteen text figures. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS is an eminently succinct and practical exposition of the subject of infant feeding. The author follows Finkelstein's method in classifying the common nutritional disorders of infants; indeed one may characterize his book as an excellent English version of the modern German theories of pathological nutrition in infancy. Simplicity is the keynote in the various methods of feeding advised for healthy and sick infants. One cannot but admire the absence of arbitrary rules and the recognition of the fact that the correct feeding of any infant must be established by experiment. In using the term "albumen-milk" as the English equivalent for eiweissmilch the author commits a common error of nomenclature. This preparation is more correctly named protein, or casein-milk. This error is one of minor importance, however, and in no sense mars the value of this book. The four plates illustrating four different types of infant's stools are unique in their graphic portrayal of a subject that is inadequately described in words.

Simplified Infant Feeding. With Seventy-Five Illustrative Cases. By Roger A. Dennett, B.S., M.D., Adjunct Professor of Diseases of Children, New York Post-Graduate Medical School; Attending Physician of the Children's Department New York Post-Graduate Hospital; Assistant Attending Physician at the Willard Parker Hospital and the Red Cross Hospital, New York. With 14 Illustrations. Price, $3.00. Philadelphia and London: J. B. Lippincott Company, 1915.

There are several unique features about this book. As its title indicates, it attempts to simplify infant feeding: instead of the complicated formulae of milk, cream, and water, it recommends the use of mixtures of milk and water with the addition of cane sugar. The seventy-five illustrative cases which bring the subject before the reader in a concrete form deal with different types of difficult feeding and their management. In discussing the various phases of nutritional disturbance in infancy the author follows closely the modern German classification. An excellent and complete synopsis of the entire text is given at the beginning of the volume. The author notes that when boiled milk is used in infant feeding curds are less apt to appear in the stools. He details five different methods of treating diarrhea. Special chapters are devoted to the subjects of constipation, vomiting, loss of appetite, combined breast and bottle feeding, etc. This book has many merits, but there is room for improvement, particularly in its literary style. As examples of careless English the following two paragraphs from the preface may be cited: "There has been so much written upon the theory of infant feeding that the general practitioner is lost in its mazes, since the theories are constantly changing and eminent pediatricians differ so widely in their ideas upon the subject." "That is the reason that 'theory' has been left out of this book as much as it has been possible to do so, using facts and rules when they can be made to apply." The word "proteid" is used generally throughout the book, although the correct term "protein" is also used in some places. The literary shortcomings are, however, of minor importance in comparison with its many admirable features. The typography, illustrations, and binding are particularly good.

Occupational Affections of the Skin. A Brief Account of the Trade Processes and Agents Which Give Rise to Them. By R. Prosser White, M.D., Ed., M.R.C.S., Lond.; Life Vice-President, Senior Physician, and Dermatologist, Royal Albert Edward Infirmary, Wigan; Vice-President, Assoc. Certif. Fact. Surgeons; Life Fellow, Lond. Dermat. Society; Member Manch. Med. and Dermat. Society; Hon. Life Member, St. John's Ambulance Assoc.; P.M.C. and Senior Surgeon, Church Lads' Brigade. Price, $2.00 net. New York: Paul B. Hoeber, 1915.

A definite gap in the literature of medicine is filled by this volume, which consists of a compilation of practically all that is known about the occupational diseases of the skin—a subject to which considerable attention has been paid within recent years. Chapter I is headed "A Circumspection" and deals with such topics as nomenclature, statistics, protective resources of the skin, diagnostic and stigmata, clinical varieties, etc. Chapters II, III and IV discuss various trades, chemicals and processes. Chapter V deals with petroleum and tar distillation, and Chapter VI, with aniline. Dermatitis venenata comprises the subject matter of Chapter VII, while the concluding chapter of the book deals with zoetic dermopathy. The book is printed on excellent paper in clear type, the various processes and agents being given in heavy-face type. There are a number of excellent illustrations. The index is particularly full, a fact which renders this book valuable for quick reference.

Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarzt für Ohren-, Nasen-, und Halskrankheiten in Ludwigshafen a. Rh.; Dr. H. Preysing, Prof. der Ohren, Nasen, Kehlkopf,Heilkunde, Ord. Mitglied der Akad. für prakt. Medizin zu Cöln a Rh.; und Dr. F. Blumenfeld, Spezialarzt für Nasen-, Hals-, und Lungenkrankheiten in Wiesbaden. II Band, Lieferung 3. Price, 7 marks. Würzburg: Curt Kabitzsch, 1914.

The Intrapharyngeal Surgery of the Nasopharynx is the opening article of the present number and is from the pen of P. H. Gerber. It comprises a section of 36 pages and is accompanied by four handsome colored plates, in addition to the other numerous illustrations. E. Kronenberg contributes the next article of 80 pages on the Surgery of the Mouth. Seven superb colored plates accompany this article. They illustrate chiefly different types of new growths of the lips and tongue. The Diseases of the Base of the Tongue is the title of an article also contributed by Kronenberg. Suspension Laryngoscopy is described in a fully illustrated article by Hölscher. This number of the "Handbuch" maintains in every respect the high scientific and artistic standard set by those that have already been published. The statement is made on the cover that the remaining numbers of the second volume "will appear after the end of the war," and it is to be hoped that they will appear very soon.

What the Mother of a Deaf Child Ought to Know. By John Dutton Wright, Founder and Principal of the Wright Oral School for the Deaf, New York City; Collaborator of the "Laryngoscope" and the "Volta Review"; Director of the American Association to Promote the Teaching of Speech to the Deaf; Author of "Eucational Needs of the Deaf," for the Guidance of Physicians. Price, 75 cents. New York: Frederick A. Stokes Company, 1915.

The keynote of this little book is struck when the author states in the preface that "even though the child be totally deaf from birth, he can nevertheless be taught to speak and understand when others speak to him. He can be given the same education that he would be capable of mastering if he could hear." In a series of twenty-seven short and succinct chapters the mother is given instruction as to her duties toward her deaf child, particularly during the years preceding the school age. She is told how to test the child's sound faculties and how to determine the degree of learning that may be present. The child may be made to understand and may be taught to speak many words and sentences by watching the facial expression and lips of the mother. The child's mental faculties may be developed with the aid of the Montessori method. He should be taught to play games and use toys that exercise the lungs. The creative imagination may be developed with the aid of modeling wax and building blocks. The mother is instructed how to develop any residual hearing that the child may possess. His power of lip reading should be trained. The formation of character and the cultivation of the social instinct must not be overlooked. The following subjects are also discussed. The preservation of speech when deafness results from accident or illness after infancy; teaching lip reading; school age; organized efforts by parents to obtain better educational conditions; the personal cooperation of the parent in the teaching of deaf children; day schools; the deaf child at five years of age; schools for the hearing and private governesses; importance of the beginning; avoid the young and inexperienced teacher; on entering school, with instructions for the guidance of the mother during the child's first year at school, by Eleanor B. Worcester; during the school period; during vacation; and some "nots." The book is an inspiring exposition of a subject that has hitherto been sadly neglected.

A Manual of Personal Hygiene. Proper Living upon a Physiologic Basis. By American Authors. Edited by Walter L. Pyle, A.M., M.D.; Member of the American Ophthalmological Society; Fellow of the American Academy of Medicine; Fellow of the College of Physicians of Philadelphia; Assistant Surgeon to the Wills Eye Hospital, Philadelphia, etc. Sixth Edition, Revised and Enlarged. Price $1.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

Among the special articles in this manual of hygiene for the general reader, which add considerably to its authoritative value, are the following: Hygiene of the Digestive Apparatus, by Chas. G. Stockton; Hygiene of the Skin and its Appendages, by George Howard Fox; Hygiene of the Vocal and Respiratory Apparatus, by E. Fletcher Ingals; Hygiene of the Ear, by B. Alex. Randall; Hygiene of the Eye, by Walter L. Pyle; Hygiene of the Brain and Nervous System, by J. W. Courtney; Physical Exercise, by G. N. Stewart; the Body Posture, by J. E. Goldthwait; Domestic Hygiene, by D. H. Bergey; and Food Adulteration and Deterioration, by Harvey W. Wiley. There are also a chapter on the Hygiene of Infancy and an Appendix containing information on baths, massage, accidents and emergencies, etc. The book is a practical exposition of the subject of personal hygiene in accordance with the latest teachings.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-fifth Annual Meeting held at Philadelphia, September 20-25, 1915.

THE PRESIDENT, DR. EDWARD B. HECKEL OF PITTSBURGH, IN THE CHAIR.

THE meeting was opened with prayer by the Rev. Marcus A. Brownson, D.D. The Hon. Rudolph Blankenburg, Mayor of Philadelphia, welcomed the Society on behalf of the city; and Dr. E. E. Montgomery, President of the Philadelphia County Medical Society, on behalf of the local profession.

Civic Responsibility of the Physician and the Medical Society.—Dr. JOHN B. MCALISTER of Harrisburg, in this, the President's Address, mentioned as vital problems for thought on the part of the State Society: The standardization of the profession throughout the country, and hoped that he might see the day when a licensed doctor in Oklahoma would be a licensed doctor in Pennsylvania. He believed that the attitude of the profession should be modified toward new schools of practice; all that was good in the various methods of relief was to be desired; ignorance and fraud only should be opposed. He believed that the legislative committee of the Society needed the wisest judgment and conscientious co-operation of the profession, and that the establishment of a Board of Regents similar to that of New York would set standards, protect the public against fraud and incompetency, remove from the profession the reproach of bigotry and selfishness, and prevent the multiplicity of examining boards. In the field of preventive medicine he felt there was great need of a National Health Department in the Federal Government. Half a million deaths in America annually from preventable disease emphasized this need. He regarded the newspaper as more powerful than all the guns of all the armies in the world and believed, did they unite, they could end the war in Europe. He felt that the press and the doctor should join forces for the education of the public in health, hygiene, and preventive medicine and for influence with legislatures. The value of organization and co-operation was emphasized.

Report of the Sub-Committee on Cancer.—Dr. JONATHAN M. WAINWRIGHT of Scranton stated his belief that the Pennsylvania State Medical Society was the first organization making a systematic attack upon the problem of cancer. The first effort had been to induce every medical college professor interested in a subject approaching cancer to impress upon his students the fundamental principles of the cancer campaign and the hope was expressed that examining boards might be induced to insist upon a proper knowledge of the disease. Effort had been made to have every nurse training school in the State have their nurses instructed in the subject. Perhaps the most efficient plan by which the Society had worked had been through the county societies. In June thirty-eight counties had held meetings devoted to the consideration of cancer, and sixty-five journals in their July issue had joined in a cancer campaign.

The Evil Effects of Delayed Operation in Malignancy.—Dr. CHRISTIAN B. LONGENECKER of Philadelphia believed that in the entire field of medicine nothing was of so great importance as early diagnosis in malignancy and in this connection the responsibility of the family physician was very great since he was the first consultant. He emphasized the necessity of physicians becoming more conversant with the early signs of cancer. He referred to cases in which the patient had been advised to "wait and see if the lump might not disappear," or "until the character of the lump could be determined." While hope lay in early diagnosis and early treatment it might be with propriety questioned whether this treatment should always be surgical. There were other agencies claiming attention and promising much, but time was required to demonstrate their value. Slides were shown of operations unsatisfactory in result although the patients had passed through competent hands.

Dr. JOHN G. CLARK of Philadelphia believed that as pioneers in the dissemination of knowledge concerning cancer the Sub-Committee of the State Society had laid an enduring foundation by first attempting to put the medical profession in the right position regarding the question. Two serious errors were delay on the part of the patient to seek advice and negligence of the physician to observe the most patent symptoms.

Pennsylvania's Relation to Industrial Safety and Health.—JOHN PRICE JACKSON, Commissioner of Labor and Industry of Pennsylvania, of Harrisburg, read this paper by invitation. He said that the Industrial Board had prepared a set of standards beginning with the problem of safety, and that it had covered a large proportion of the industrial activities of the State. It was the intention later to formulate rules relating to industrial health and sanitation. The duty of the division of hygiene and engineering was that of preparing for the industrial board information of value in reducing accidents, improving health conditions and increasing the welfare of the workers. The matter of injury to children between the ages of 14 and 16 unfitted for their work, the study of poisonous industries, the preparation of first aid kits, investigation of the effect of tobacco fumes on tobacco workers were some of the questions included in the work of the Division. The Accident Corporation System, another line of endeavor in the work of the industrial board has for its primary object the giving of prompt adequate aid to the injured for maintenance of himself and dependents.

Diagnosis of Tubal Pregnancy.—Dr. ALFRED HEINEBERG of Philadelphia considered the diagnosis of tubal pregnancy before interruption in the course of the pregnancy occurred and after its course had been disturbed in one of several ways, with a brief review of changes taking place in the pelvic structures and embryo before such disturbance and cause of failure in diagnosis in this stage. He classified cases in which interruption in pregnancy has occurred into "tragic" and "non-tragic," and mentioned pathological changes during and after interruption in each type. Symptomatology and diagnostic signs were enumerated with a consideration of the differential diagnosis from ordinary abortion, twisted pedicle of an ovarian cyst, pyosalpinx, appendicitis and other conditions causing peritonitis.

Dr. WILLIAM R. NICHOLSON of Philadelphia cited a case occurring at the Methodist Hospital approaching the "tragic" type mentioned by Dr. Heineberg. A large amount of blood had been found in the peritoneal cavity but he had been unable to find rupture or enlargement of either tube until after their delivery, when a small perforation was discovered close to the cornu. The frequency of confusion between extrauterine pregnancy and abortion he felt should be emphasized. Slight uterine hemorrhage he considered of great importance.

Dr. JOHN A. MCGLINN of Philadelphia, in reviewing the histories of eighty cases of this kind upon which he had operated had found none presenting symptoms sufficiently different from those of normal pregnancies to cause the patient to consult her physician. He believed that few cases would be diagnosed before rupture because patients would not present themselves for study until after rupture had occurred. He believed the number of cases diagnosed by the general practitioner was in direct relationship to the publicity given the subject. While he agreed practically with Dr. Heineberg regarding diagnosis at the termination of pregnancy he believed the most important aid in diagnosis was a painstaking history. Differing somewhat from Dr. Heineberg he did not believe the amount of shock to be dependent upon the size of hemorrhage; he had seen profound shock following rupture with but little blood in the peritoneal cavity, and cases with the pelvic and abdominal cavities full of blood with practically no shock.

Dr. HUGGINS of Pittsburgh in a series of more than 100 cases had diagnosed ectopic pregnancy and operated before rupture in 22 instances. He believed that if the general practitioner in seeing a patient with the history of pain in the pelvis and a missed menstrual period would think of ectopic pregnancy he would diagnose such a case in the majority of instances. He believed that ectopic pregnancy should be diagnosed in more than 85 per cent. of cases.

Scopolamine-Morphine Anesthetics in Obstetrics.—Dr. JAMES R. FREELAND of Pittsburgh classed as largely "advertising matter" the literature appearing in association with this subject in the last fifteen months. A statistical review was given of cases regarding the effect of scopolamine in relieving pain; its effect upon uterine contractions and the duration of labor; the effect upon the child and its temporary and permanent effect upon the mother. He believed the proper field

for scopolamine was that of a useful sedative in selected cases. Complete amnesia should not be regarded as the main object of its use. The physician should reserve the right to give "twilight sleep" just as the surgeon chooses the anesthetic without reference to the wishes of the patient.

Dr. Barton Cooke Hirst of Philadelphia had found the disadvantages of the method to be prolongation of labor, tendency to atony of the uterus with hemorrhage, and an increased proportion of apneic babies that could not be revived. If one followed the latest method of giving minimum doses of the two drugs, the disadvantages disappeared, hut the relief afforded was scarcely noticeable. He had, however, found the method of advantage in primiparæ of a neurotic type in whom a long painful labor was probable, and in such cases used it rather for its psychological effect than for the relief of pain. He thought it unfair to criticize negatively any method without offering some alternative. He referred to his experimental use of canabis indica for the relief of the pains of childbirth without disadvantage to mother or child.

Dr. Daniel Longaker of Philadelphia believed that every woman should be transferred to the specially appointed hospital for her confinement regardless of the method by which delivered. He believed that Dr. Freeland would eventually admit that the full benefit of scopolamine is obtained only with complete amnesia. He agreed that the apnea was due to the morphia and said that in certain cases neither of the drugs should be used.

Dr. D. M. Barr of Philadelphia referred to his employment of an anesthetic in labor consisting of one part chloroform, two parts alcohol, and three parts ether, and showed an inhaler made for him by the elder Colby forty years ago. With a means so efficient as the method had been in his hands he questioned the necessity of resort to the "Dämmerschlaf." He called attention to the publication of his paper "A Plea for Anesthesia in Labor" in the *Medical and Surgical Reporter* of 1880.

Dr. Freeland, in closing, regretted his inability to join the enthusiasts for the use of scopolamine anesthesia. His first objection was to the name "twilight sleep," by which it was usually known, regarding this as a trade name, and as such, without place in the practice of medicine. The factor of suggestion also he considered harmful to the patient's mental balance and believed that a certain proportion of patients would later come into the hands of the neurologist.

Pulmonary Tuberculosis and Pregnancy.—Dr. C. C. Norris of Philadelphia considering the frequency of pregnancy in the tuberculous said it was an undetermined point whether or not the normal, pregnant woman was more susceptible to infection by the tubercle bacilli than her non-pregnant sister. That pregnancy exerted an unfavorable influence upon the course of tuberculosis he said was generally admitted, but no hard and fast rule could be laid down. He believed it correct to advise the tuberculous woman against marriage, but here too, a hard and fast rule was too sweeping. Certainly, however, marriage should be advised against in the presence of an active lesion, no matter how limited. Regarding the treatment of pregnancy in the tuberculous the author believed that the attitude toward any given case should depend upon the individual conditions. There must be the consideration of the advancement of pregnancy, the character of the pulmonary lesion, social status and intelligence of the patient, her ability to undergo hygienic and dietary treatment and whether she already has children. Indications for the induction of abortion in the tuberculous prior to the fifth month, choice of operation, treatment of pregnancy advanced beyond the fifth month and during the puerperium were also considered.

Dr. R. H. M. Landis of Philadelphia remarked that among tuberculous women a very considerable number gave the first noticeable manifestation of the disease during the course of pregnancy. He doubted, however, if any of these cases were instances of primary infection at this period, but believed rather than they were cases of quiescent tuberculosis in which the added stress of pregnancy had lighted up the process. He had known, however, of instances in which women after six or seven years of sterility had become pregnant after recovery from an attack of incipient tuberculosis and without recurrence of the disease. This he attributed to the improved health. He was opposed to legislation advised by eugenists against the marriage of all tuberculous persons and questioned whether it could be enforced. He agreed with Dr. Norris' views concerning treatment, but disagreed with him in the use of ether as an anesthetic believing it to have a bad effect upon tuberculous lesions in the lungs.

Dr. Alexander Armstrong of White Haven said it was his custom to advise against the tuberculous woman bearing children until she had had at least five years of health. This opinion applied also to the question of marriage. He knew of no case of relapse as a result of pregnancy in a patient who had remained well for five years after the initial attack.

Dr. John A. Lichty of Pittsburgh referred to a very practical side of the question arising when, in spite of advice against pregnancy, the woman five or six months after confinement was found to be in a dangerous condition with marked evidence of infection. The impaired health was too apt to be attributed to the effect of nursing the baby. In this connection he felt the burden lay upon the internist to take serious consideration of the patient.

Dr. Elmer H. Funk of Philadelphia referred to a series of 100 cases of tuberculous women studied at the Jefferson Hospital in 43 of whom the definite lesions dated from the beginning of pregnancy and during the puerperium. Termination of the pregnancy in the early months gave better results than in instances in which they had been inclined to allow the pregnancy to proceed. In the latter stages the tuberculous lesion had rapidly increased.

Hospital and Home Isolation.—Dr. Dennett L. Richardson of Providence, R. I., read this paper by invitation. While the exact cause of many infectious diseases was unknown considerable definite knowledge concerning the escape of virus from the body had been gained through laboratory investigation and epidemiological experience. An enumeration of diseases was given with the method of escape of the infecting material. Upon the subject of extra-corporal longevity of viruses there was much difference of opinion; in media such as water and milk they might survive and even multiply. Available data practically ruled out atmospheric contagion. The underlying principles of control of infectious diseases by home isolation should be the same as in the hospital. Simple methods of protection of other members of the family should be utilized in place of elaborate hospital equipment. The human being himself was said to be the chief distributor of the disease. Three sources of disease in the community were persons recognizedly sick with infectious disease; missed cases; and the carriers. He believed it erroneous to suppose that a room occupied by a patient with an infectious disease was permeated by the virus. That fumigation was unnecessary had been shown by Dr. Chapin at Providence and by the recent experiments in New York City. In Providence terminal disinfection after diphtheria was abandoned in 1905, except in a few instances.

Quarantine of the Home as Practised by the Department of Health in Pennsylvania.—Dr. Samuel G. Dixon of Harrisburg enumerated the reasons for the various types of quarantine established, details of community quarantine and domiciliary quarantine, pointed out the differences between modified quarantine and absolute, conditions under which wage earners' permits may be granted with quarantine over the premises, etc., and the changes in quarantine under the new law.

An Unappreciated Form of Pneumothorax.—Dr. Charles Rae of York read this paper. By this "unappreciated form of pneumothorax" was meant that form which came on suddenly without obvious evidence of illness. The condition was considered to be due to rupture of air vesicles from a tearing of the pleura, probably always due to a previous pleurisy resulting in an adherence of the two surfaces. Frequency was rather greater than generally supposed, and the condition more familiar to radiologists than to other workers. The differential diagnosis would be of interest so far as extreme emphysema was concerned. General care would seem to be all the treatment required. There should be avoidance of any unnecessary muscular effort until absorption of the air and obliteration of the rent had taken place. While prognosis was excellent in the majority of cases some instances had been reported in which absorption of the air had not occurred for many years. Literature showed the occurrence of outspoken pulmonary tuberculosis in several cases of the condition.

Therapeutic Pneumothorax in Pulmonary Tuberculosis.—Dr. Alexander Armstrong of White Haven said

this method of treatment had been used at the White Haven Sanatorium for three years and the results in sixty cases were given. The procedure consisted of the introduction of gas, preferably nitrogen, into the pleural sac, compressing and eventually collapsing the affected lobe or lung. Strict asepsis was to be enjoined throughout the operation. The lung was usually kept under compression for six months although in some cases a longer time was essential. The rationale of the measure was to lessen expansion of the alveolar tissue and to encourage drainage of septic matter. Three indications for the treatment were: (1) Progressive softening in one or more lobes of one lung, the other lung being normal; (2) relief of hemorrhage; (3) pleurisy, either dry or with effusion. While a careful selection of cases was advisable it was not necessary to restrict the treatment to those in which the disease was unilateral.

Dr. CHARLES M. MONTGOMERY of Philadelphia believed that "unappreciated pneumothorax" described by Dr. Rae should have been more readily recognized by the profession than had been the case. He knew of no more encouraging paper in literature upon the subject than that of Dr. Armstrong's giving the excellent results. It was a matter of concern lest the impression might be conveyed that the operation was a simple one and its employment not limited to experts in the work.

Dr. ISADORE KAUFMAN of Philadelphia pointed out that Dr. Rae's case of pneumothorax had occurred in a tuberculous individual and stated his belief that a very large percentage of the cases developed in phthisical patients. His experience was limited to two cases and in both the condition disappeared in a few weeks. All of Dr. Armstrong's conclusions regarding therapeutic pneumothorax agreed with his own.

Dr. D. M. BARR of Philadelphia discussed the value of hot air in medicine administered by inhalation and exhibited an inexpensive instrument which he had devised by which air could be heated to 400° F. Cases were cited in which diseases of the chest had been corrected by the inhalations.

Medical Education in China.—Dr. JAMES B. NEAL of Tsinan, China, presented (by invitation) this paper in which he brought greeting to the Medical Society of the State of Pennsylvania from the China Medical Missionary Association the membership of which was made up of four or five hundred doctors in China, principally American and British. The development of medical education in China had been left almost entirely to medical missionaries. In addition to the work already done by the Medical Missionary Association it is planned to have at least one thoroughly equipped medical school in China in which the teaching shall be done in Chinese. Dr. Neal pointed out that there was in China an immense field for not only medical work, but for the training of Christian doctors. Under the Rockefeller Foundation there would be a great demand for Christian medical men to help in the training of a medical profession for China.

Cholesteatoma of the Spinal Cord.—Drs. WILLIAM EGBERT and SAMUEL D. INGHAM of Philadelphia reported this case. The patient was a young woman taken from school when 15 years of age because of increasing languor and anemia. She was first seen on December 28, 1914. There were progressive loss of flesh, intermittent insomnia, motor and sensory disturbance of the left leg, later of the right, variable in character, obstinate constipation, marked cystitis, and a mixed spastic and steppage gait. At operation on March 31, 1914, by Dr. W. Wayne Babcock a tumor 5½ inches long was removed which microscopic examination showed to be a cholesteatoma. The patient has gained 25 lbs. in weight. There was still moderate foot drop in the left leg with a little anesthesia and loss of muscle sense, but there was considerable gain in power with increased size of the left leg and gait was almost normal.

Comparative Therapeutic Effect of Mercury and Salvarsan in Experimental Trypanosomiasis.—Drs. JAY F. SCHAMBERG, JOHN A. KOLMER, and G. W. RAIZISS of Philadelphia contributed this paper, which described studies of the toxicity of the soluble and insoluble mercurial compounds, of distribution of mercury in the animal body, and the resultant pathological changes. The effect on trypanosome infections of various mercurial salts was given with studies of the toxicity of salvarsan and an investigation of its trypanicidal influence. The chemistry of salvarsan was considered, with an interpretation of the above findings and their application to the treatment of syphilis.

Factors Influencing the Present Mortality in Peritonitis.—Dr. DAMON B. PFEIFFER of Philadelphia stated that there was a marked reduction in the mortality in peritonitis during the past few years due to recognition of the principle of early operation and to evolution of improved operative methods. The present medical treatment founded upon incorrect reasoning and older teaching was responsible for a large part of the present mortality. It was urged that practitioners adopt methods which surgeons have found to be most efficacious in the general treatment of peritonitis. The author discussed the simplicity and rationale of these methods.

The Value of the Psychopathic Hospital.—Dr. D. J. MCCARTY of Philadelphia referred to the need of a better equipment for the care, study, and the prevention of mental disease. He would divide the psychopathic hospital into: (1) The clearing house type for the reception and distribution of mental cases; (2) the psychopathic, the primary function of which was for the investigation of mental cases; (3) the psychopathic hospital for the cure of border-line cases. There should be facilities in every general hospital for the care of temporary cases of mental disease. He would favor also a preventorium type of institution for the reception of all types of disease needing rest, fresh air, physical training, occupation, open to border-line cases and the functional types of nervous cases, latent tuberculosis, functional and early organic heart, liver, kidney diseases, etc. All such institutions should have departments for partial and full pay in addition to provision for the State charges.

Dr. JAMES HENDRIE LLOYD of Philadelphia said that the term "psychopathic hospital" had come to be a favorite one at the present time and much used by persons of an optimistic turn of mind. It was meant to note progress, and was used to signify an institution which was different and theoretically better than the thing meant by the old-fashioned term, "insane asylum." In so far as the term meant progress it was commendable. Progress did not, however, depend upon mere words. A psychopathic hospital was after all nothing but a hospital for the study and treatment of the insane; one should not be deceived by a name; the treatment of the insane should be practically the same in all hospitals. He believed that a large municipal hospital offered the equipment and facilities desirable for mental cases.

Dr. GEORGE E. PRICE of Philadelphia did not agree entirely with Dr. Lloyd that the psychopathic hospital should be entirely under the care of the municipality. The great difficulty in the present situation was that people of moderate means have no hospital to which they could go but the municipal hospital at Blockley. He believed that every large general hospital, particularly those connected with the teaching institutions should make provision for the mentally sick, just as they would for the man with an acute pneumonia or nephritis. The case could be received and studied and then provision should be made for them to meet the indications.

Dr. ALFRED GORDON of Philadelphia made a plea for the many persons seeking medical advice who were not insane in the true sense of the word and yet not normal mentally; such persons were seen who, though free from delusions and capable of reasoning, were in a state of mental disquietude and caused anxiety to their friends. For these he felt there should be a place between the general hospital and the hospital for the truly insane. There should be considered also the social nature of the question, for in spite of the teaching that insanity is a disease a stigma attaches to the placing of a patient in an asylum for the insane.

The Treatment of Exophthalmic Goiter by Means of the Röntgen Rays.—Drs. GEORGE E. PFAHLER and J. D. ZULICK of Philadelphia believed that the trial of treatment for one series with an interval of waiting of one month was justifiable in all cases, for if operation were decided upon nothing was lost, and many operations might be avoided. Treatment should be directed toward both the thyroid and the thymus glands. An increase in weight and a decrease in pulse were the first signs of improvement and were practically always found. Treatment should not be prolonged over too great a period or hypothyroidism might be produced. The goiter and the exophthalmus were the last to show improvement and in many cases showed no change.

Dr. ARDREY W. DOWNS of Philadelphia, in experimental work by the administration of thyroid gland to rabbits until hyperthyroidism appeared had been able to produce hypertrophy of the thymus gland in seven out of nine cases. While the number was too small to

have definite value, taken in connection with similar reports he inclined to the belief of an intimate relationship between the thyroid and thymus glands. He questioned whether it might not be possible that a persistent thymus gland, stirred to activity by over excitement, anemia, etc., was the real cause of exophthalmic goiter. The necessity for accurate dosage of the Röntgen rays was emphasized.

(To be continued.)

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-eighth Annual Meeting, Held at Pittsburgh, September 14, 15, and 16, 1915.

THE PRESIDENT, DR. CHARLES L. BONIFIELD OF CINCINNATI, IN THE CHAIR.

(Concluded from page 677.)

The Use of Luteum Extract in the Treatment of Menstrual Disorders.—Dr. ADAM P. LEIGHTON, JR., of Portland, Me., after reporting several cases of menstrual disorders, said that from his little experience, he was certain that there were cases of dysmenorrhea in which the main causal factor was deficient action of the natural *corpus luteum*. He was not carried away with the idea that the therapy of *corpus luteum* was a cure-all in any sense of the word. On the other hand, the cases which might be traced to ovarian deficiency were probably in the distinct minority. One must not allow himself to be so impressed with the etiological value of some one factor in the cause of disease, that he forgot or became indifferent to others of equal importance. Surgery was necessarily indicated in those cases where they found pelvic pathological conditions or anatomical abnormalities present, which they were wont to consider as probably causes of this disorder. There were some serious drawbacks to the use of *corpus luteum*. It generally had to be used routinely or continuously to obtain and maintain results. Its cost injured its more general application. Its action was not immediate, it was cumulative, and for that reason patients and they themselves too often discarded its use after a short trial, if it had been unproductive of good results. As regards its dosage, he found that from fifteen to thirty grains a day, seldom more, were sufficient in any case. Its prolonged administration had not brought about any untoward symptoms, that he had been able to detect, with the possible exception of slight gastric disturbance in one or two instances. The subject of organotherapy, in its present experimental state, was rather involved and indefinite, and while it was sometimes difficult to recognize and identify cases which would be benefited by *corpus luteum*, yet when there was a possibility of ovarian deficiency being an etiological factor in any gynecological disorder, they owed it to the patient to make use of this remedial agency, for its value was well determined.

The Present Status of Twilight Sleep in Obstetrics, Based upon a Collective Study of over 2,000 Cases.—Dr. A. J. RONGY of New York City, after referring to 2,000 cases which he had collected from the literature, said that, judging from his personal experience extending over a period of fifteen months and covering a series of over 350 cases, he felt that the value of the treatment and its acceptance as a recognized therapeutic measure would depend upon our interpretation of the physiological processes which were produced by these drugs. If we accepted the theory that the semi-consciousness induced, prevented the actual experience of pain, although apparently present in all its clinical phases, then labor must be considered painless, and therefore to refuse to adopt it would be a failure on our part to carry out the trust reposed within us. On the other hand, if the mental state induced did not actually prevent the sensations of pain and the patient was actually suffering, even though it be modified, then the value of this method would devolve upon the degree of pain, diminution of analgesia, and not upon the lack of recollection of pain or amnesia. He found it difficult to reconcile the fact that a patient, displaying all clinical evidences of pain, such as crying and groaning, as was observed in these patients, did not actually experience it. However, he was fully convinced that pain in a goodly proportion of cases was influenced to a degree that would warrant its adoption in selected cases, more particularly in the primiparæ of the highly emotional type and in multiparæ in whom we anticipated long and tedious labors.

Dr. JOHN NORVAL BELL of Detroit, Mich., reported an unusual case of myofibroma complicating pregnancy in a woman, 31 years of age, who had been married four years.

Chorioepithelioma.—Dr. BEN R. MCCLELLAN of Xenia O., stated that chorioepithelioma was more common than generally recognized. He emphasized the importance of a case history and the laboartory findings. Anemia might be a possible factor in the etiology as well as a result of this disease. He reported a case of a typical chorioepithelioma in which he resorted to curettage, with an apparent recovery of the patient.

Dr. ORANGE G. PFAFF of Indianapolis reported a case of fibroid tumor which completely obstructed the uterine canal; dead fetus long retained without infection.

The Teaching of Obstetrics.—Dr. CHARLES EDWARD ZIEGLER of Pittsburgh said he would not overemphasize the importance of didactic teaching in obstetrics. It was basic and indispensable to the teaching of obstetrics as a science. It must in part precede and in part accompany clinical teaching, but could never take its place as had too long been attempted. In times past, obstetrics was taught very largely didactically and in certain quarters this was still the case. Even at the present time in all but a few medical schools in this country, the clinical teaching and practical experience given undergraduate students in obstetrics were woefully deficient. Both the teaching and practice of obstetrics were generally regarded as the poorest of all the clinical branches of medicine. There must be a reason for this. Any scheme for improvement in obstetric teaching and practice which did not contemplate the ultimate elimination of the midwife would not succeed. He said this not alone because midwives could never be taught to practice obstetrics successfully, but most especially because of the moral effect upon obstetric standards. The lay public would continue to regard with indifference all pleas for the improvement in the teaching of the practice of obstetrics so long as more than 50 per cent. of confinements were in the hands of ignorant, non-medical individuals, who as a class were regarded as capable of doing the work satisfactorily even by physicians, among whom were certain well known professors of obstetrics. The teaching of the clinical or practical side of obstetrics could be accomplished satisfactorily only through the medium of suitably equipped and properly conducted hospitals and dispensaries. Such hospitals and dispensaries should be teaching and research institutions in the fullest and broadest sense of the terms, with a large amount of obstetric material freely and constantly available for the purpose. The teaching staff, and there should be no other, should consist of full time workers only, who should be paid salaries sufficiently large to make them independent of all other work. To become a thoroughly trained obstetrician, the graduate student must spend a number of years as assistant and teacher in maternity hospital and dispensary services of the type described. The major part of undergraduate instruction should be given by graduate students for this very purpose. The teaching helped them immeasurably. It gave them assurance, made them alert, taught them the invaluable art of expression, and developed clean-cut ideals and thorough-going accurate procedure. Laboratory studies and research should constitute an indispensable part of all graduate study in obstetrics, not alone for the knowledge which the student acquired and what he added to the knowledge of the subject, but most especially because of the habit of investigation acquired thereby, which would make him fruitful in research later and prevent him the more certainly from degenerating into a mere money maker.

The Combined Operation for the Interruption of Pregnancy and Sterilization.—Dr. PALMER FINDLEY of Omaha after reporting four cases, drew the following conclusions: (1) The combination of abdominal hysterectomy and resection of the Fallopian tubes was the procedure of choice in all cases not previously infected. (2) The removal of the ovum through an abdominal incision should be reserved for those cases in which permanent sterilization was desired. (3) No other method was so free from the dangers of sepsis, retained secundines, perforation of the uterus and excessive loss of blood. (4) In point of safety, expediency, and efficiency, the procedure would appeal to all abdominal surgeons.

Surgical Operations during the Pregnant State.—Dr. FRANCIS REDER of St. Louis stated that his conclusions gleaned from the studies of a limited experience with surgical lesions complicating or coexisting with pregnancy could be expressed briefly, as follows: A woman expecting to become pregnant should be thoroughly examined for any physical defect that might be found. Such a defect should be corrected, if possible, before pregnancy took place. No operation that could be deferred should be performed upon a pregnant woman. Any operation that would contribute to the safety of a pregnant woman should be performed without hesitancy.

The Value of Pituitary Extract in Obstetrics and Gynecology.—Dr. SAMUEL W. BANDLER of New York City spoke of the value of pituitary extract in labor. He referred to its importance as a diagnostic test to distinguish between false and true labor pains. It was a great help in cesarean section. In gynecology it served a good purpose in certain menorrhagias and metrorrhagias. It was of aid in postoperative atony of the intestine and bladder, etc.

Menstrual Statistics Based on a Study of 4,500 Menstrual Histories.—Dr. K. I. SANES of Pittsburgh stated that 75 per cent. of women menstruated regularly and 25 per cent. irregularly. The most common regular type met with was that of twenty-eight days, which constituted 72 per cent. of this type. The thirty-day type followed next in frequency with only 3.8 per cent., and the twenty-one day type with 3.3 per cent. etc. In some of the thirty-one days' type the menstrual flow appeared monthly on the same date independent of the number of days in the month. The most common irregular types were three to four weeks, then four to five weeks, two to three weeks, five to six weeks, etc. The most common ages of onset in order of their frequency were 15, 12, 16. The age of onset did not show any relation to regularity or irregularity of menstruation. The earliest age of onset in our series was 9 years and the latest 24 years. The most common duration of menstrual flow was three days, then four to five days, three to four days, five days, seven days, and four days. The irregular type of menstruation showed a larger percentage of long durations and smaller percentage of shorter durations, than the regular type. The quantity of flow in 45 per cent. of women was normal, in 17 per cent. scant, and in 37 per cent. profuse. Irregular patients showed a higher percentage of profuse flow than the regular ones. Hyperthyroidism cases showed a very high percentage of profuse menstrual flow (65 per cent.). Clots were very frequently found in menstrual flow and they did not find them to be influenced by menstrual irregularity. Forty-seven and four-tenths per cent. of women suffered from dysmenorrhea (if the term dysmenorrhea was to convey the idea of discomfort). In retrodisplacements the percentage was found to be 50.4 per cent. In 50 per cent. of the dysmenorrhea cases the symptoms appeared during the flow, in 29 per cent. before, in 17 per cent. before and after, and in the rest after the flow or during and after. Most frequently the dysmenorrhea appeared the day before the flow, then the first day of the flow, then two days during, two days before, one day before and two days during, then three days before, and seven days before. Improvement in menstruation was frequently noticed with advance of menstrual life, after marriage and after childbirths, menstrual periods becoming more regular and the dysmenorrhea improving or disappearing entirely. The most common ages of menopause in order of their frequency were given as 50, 46, 48, 47, 51, 49, 44, 45, 52. The length of menstrual life was most commonly given as 37 years, then 35, and 33. Sixty-eight per cent. reported a menstrual life of 30 years or more. The very early and very late ages of puberty showed a rather early menopause.

Anesthesia in Gynecological Operations.—Dr. R. R. HUGGINS of Pittsburgh, said all methods should be used with discrimination and judgment and when this was done by those who had the knowledge to select the cases the mortality and morbidity of anesthesia would be materially lessened. There could be no doubt that gaseous drugs should be administered in exact amounts and this could be accomplished only by a physical measuring instrument which indicated accuracy, not only to the anesthetist but to the operator as well, the percentage of drug which was being inhaled. When this method was established, the safety and efficiency of surgical narcosis was increased and the shock and postoperative discomforts were reduced to a minimum. Occasionally he found the narcosis anesthesia of value and he practically always preceded his local and spinal anesthesia with injections of hyoscine and morphine which allayed the patient's nervousness and removed any objection to consciousness during operation. It was not at all unusual to have the patient sleep throughout the operation, if not disturbed. This preliminary dammerschlaf was particularly valuable in operations under local or spinal anesthesia in highly nervous or insane patients. The value of nitrous oxide supplemented by local anesthesia had been demonstrated by Crile. There was no doubt that shock was reduced to a minimum. The value of Crile's theory so far as it went, led to the consideration of the advisability of blocking the nerves either by injecting the solution into the nerves where they escaped from the spinal canal or in selected cases the use of spinal or lumbar anesthesia. It seemed reasonable that if the technique that partly blocked the nerves was valuable, one that went to the fountain head completely blocking the entire nerve supply must be more so. A careful study of the literature led to the conclusion that it had passed through a very stormy period. Extreme enthusiasm which led to unfortunate results had given way to a sane appreciation of its value when used with caution and full knowledge of its contraindications. After an experience with spinal anesthesia covering a period of two years the writer was convinced that it was of great value and that it would eventually find a high place among the methods of anesthesia, particularly for surgical procedures in the lower abdomen and pelvic cavity. The time was not here, however, when it could be used indiscriminately and by those who were not familiar with the contraindications. It was highly important to know when not to use it. A keen appreciation of its dangers and the unfortunate sequelae which had thus far caused considerable prejudice against the method would enable us to avoid its use in certain instances where they were liable to occur. Its wonderful possibilities would then overshadow the disadvantages, and when trouble was encountered the operator would be able to charge it to his own shortcomings and not to the method.

Colloidal Therapy in Sepsis.—Dr. G. VAN AMBER BROWN of Detroit, said the laboratories in France had prepared through electrical current a colloidal silver called electrargol. This preparation had another excellent property besides being a colloid. It was heterogeneous, including two essential parts—a liquid medium and solid particles. These solid particles were seen only by ultramicroscope on a dark ground. A multitude of particles moved in the solution, each of which had an electrical charge. Every ion had its own antiseptic power. What did we expect from an ideal general antiseptic? First, a real and complete catabolic action of bacteria. Second a protecting influence on the body by stimulation of leucocytes to phagocytosis. From this viewpoint the colloidal silver was ideal. He obtained virulent streptococci from a manufacturing firm and made cultures in ascitic bouillon, putting only five drops of the silver colloid into a tube of ascitic fluid. No growth was obtained. He sprayed it onto a growth of bacteria on ascites agar plates. He transplanted the islands which came in contact with it and those which did not, and obtained growths in the culture tubes from those that did not come in contact with the spray but no growth from the others. Electrargol had in the last few years been much used in different septic conditions, not however, so far as he knew, in the bacteriemias. Here the results were very satisfactory. In his paper he cited four cases in detail in which he obtained very gratifying results. If the demand of an ideal treatment to conquer septic disease was one having a catabolic action on the invading organism, and a stimulating action on the body's defensive matter, then from this point of view the colloidal argentum was the ideal, since its germicidal action was shown both *in vitro* and *in vivo*, and the simulation of the leucocytes was also shown, a potent factor in the defense.

Syphilis Among Negroes and Whites.—Boas finds that 5 to 6 per cent. of the negro patients in hospitals are diagnosed as syphilitic, and that 3 to 4 per cent. of the white patients in these same hospitals are diagnosed as syphilitic. From 19 to 27 per cent. of skin diseases among negroes are due to syphilis; among whites from 9 to 12 per cent. Among insane negroes syphilis is apparently three times as frequent as among insane whites.—*Social Hygiene.*

State Medical Licensing Boards.

Massachusetts State Board of Registration in Medicine.

September, 1914.

ANATOMY AND HISTOLOGY.

1. What anatomic structures are involved in the problem of fallen arches?
2. Describe the semicircular canals.
3. Give an outline of the regional anatomy of the neck.
4. Give a description of heart muscle.
5. Describe the hip joint.
6. What bones are involved in so-called Colles' fracture?
7. Describe the pancreas.
8. Give the distribution and arrangement of the blood-vessels of the kidney.
9. Describe the patella, giving its relations and attachments.
10. What are sesamoid bones and where found?

PHYSIOLOGY AND HYGIENE

1. What is the function and appearance of lymph?
2. What dietary conditions influence favorably or unfavorably the development of the teeth?
3. Describe and give the functions of the cellular elements of the blood, excepting the red blood-cells.
4. How and why do changes of temperature influence the functions of the kidneys?
5. What insects are dangerous to health? How should they be dealt with?
6. What changes result in muscle tissue following a diminished blood-supply?
7. What happens if the thyroid gland is removed?
8. What part of the brain is affected when a patient has aphasia?
9. How is acidity of the stomach maintained?
10. Describe the method of counting blood-cells.

PATHOLOGY AND BACTERIOLOGY.

1. Explain the phenomena of active and passive hyperemia.
2. A patient has an acute septicemia. What changes would be found in parenchymatous organs?
3. A patient dies of pyemia. Describe the kidney in such a case.
4. A person dies of abscess of the liver. Explain what may have caused this condition.
5. What would cause thrombosis of the mesenteric vessels?
6. Give the pathology of the different common forms of cystitis.
7. Give the pathology of elephantiasis.
8. Describe the blood in a case of myelogenous leucemia.
9. Give the pathology of malaria.
10. Describe the hookworm.

ANSWERS.

ANATOMY AND HISTOLOGY.

1. In *fallen* arches, the following structures are involved: The longitudinal and transverse arches are both flattened. The muscles and ligaments of the sole of the foot are stretched; this includes the calcaneo-cuboid and the inferior calcaneo-scaphoid ligaments, the tendons of the tibialis anticus and posticus, and the flexor longus digitorum and flexor hallucis (and other short) muscles. The astragalus drops, the astragalo-scaphoid joint projects, the sole of the foot is everted, and the tendons of the peronei muscles are rigid.

2. The *semicircular canals* are three arched osseous canals, situated in the internal ear, placed above and behind the vestibule, opening into that chamber by five rounded apertures, two adjacent canals having a common opening. Each canal forms about two-thirds of a circle, and presents at one end a dilated part, the ampulla. Two of the canals are vertical, and the third is horizontal. The superior canal is vertical, and forms a projection on the upper border of the petrous part of the temporal bone. The inner extremity joins the opening of the posterior canal. The posterior canal is vertical, its upper end being joined to the lower opening of the superior canal. The horizontal or external canal is the smallest of the three, and lies horizontally just above the level of the fenestra ovalis.—(*Aids to Anatomy.*)

3. "The *region of the neck* is limited below and in front by the upper margin of the sternum, and by the clavicle on each side, while, behind, there is no sharp line of demarcation between it and the back. Above it is bounded by the lower margin of the mandible, by lines drawn from the angle of the jaw on each side to the root of the mastoid process, and by the superior curved lines of the occipital bone. The neck region is divided into well-defined anterior and posterior areas by the two sternomastoid muscles. These muscles lie close together at their origin below, but diverge widely when traced up toward their insertion into the mastoid processes and into the superior curved lines of the occipital bone. Below, the clavicular and sternal heads of the muscle are distinct from one another, and are separated by a small depression which extends upward for an inch or more above the clavicle. Higher up, however, they completely fuse into a single belly, the anterior fibers of which are derived from the sternal head, and the posterior of which principally represent the clavicular head. The anterior area of the neck lies in front of these muscles, and is triangular in shape, with the apex below at the suprasternal notch, and the base above extending from one mastoid process to the other. The posterior region behind these two muscles is also triangular in shape, with a blunted apex above at the occipital bone, and with its base below where the neck and back become continuous with one another."—(*Moorhead's Surface Anatomy.*)

4. "The muscular substance of the heart is composed of transversely striated muscular fibers, which differ from those of voluntary muscle in the following particulars, viz.: their striations are less distinct; they have no sarcolemma; they branch and unite by their branches and also at the side with neighboring fibers, and their nuclei lie in the substance and often near the center of the fibers. Moreover, the fibers are composed of a series of short cylindrical cells joined together end to end, each corresponding to one of the nuclei. The lines of junction of these cells may sometimes be seen in longitudinal sections stained with hematoxylin; but they come much more distinctly into view in sections of the fresh tissue stained with nitrate of silver. They appear to be bridged across by fine fibrils."—Schäfer's *Histology.*)

5. The *hip-joint* is an enarthrodial joint, formed by the head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the ligamentum teres. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The ileofemoral or Y ligament, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ileum, and below to the anterior intertrochanteric line. (3) The ligamentum teres. (4) The cotyloid ligament, which deepens the acetabulum, and bridges over the cotyloid notch, being there called (5) the transverse ligament. The joint has a very extensive synovial membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction, and rotation.

6. Colles' fracture is a fracture of the lower end of the radius.

7. *Pancreas: Length*, 6 to 8 inches. Consists of a body enlarged to the right at its head, with which the body is connected by a narrow part or neck, and narrowed to the left where it ends as the tail.

Position.—Placed in the epigastic and both hypochondriac regions, directed transversely across posterior wall of abdomen.

Relations of the body:—

In front. Stomach and small omentum.

Behind. Aorta, crura of diaphragm, splenic vein, left kidney, left suprarenal body, and left renal vessels.

Upper border. From right to left; cœliac axis, splenic artery.

Lower surface. From right to left; superior mesenteric vessels, inferior mesenteric vein, transverse colon.

Left end or tail. Touches lower part of anterior surface of spleen.

Right end or head. Embraced by three parts of duodenum, from which it is partly separated, behind by bile-duct, and in front by pancreatico-duodenal arteries. Is covered in front by the lesser sac of peritoneum.

Behind it lies on the first and second lumbar ver-

tebræ, from which it is separated by the crura of the diaphragm, inferior vena cava, superior mesenteric vessels, and portal vein. The superior mesenteric vessels overlap the left end of the head, lying in a groove on this surface.

Duct (canal of Wirsung): extends transversely from left to right, opens into second part of the duodenum in common with the ductus communis choledochus.

Arteries: pancreatic of splenic, superior pancreaticoduodenal of hepatic, and inferior pancreatico-duodenal of superior mesenteric.

Veins: open into splenic and superior mesenteric.

Nerves: from the solar plexus.—(*Aids to Anatomy.*)

8. *Blood vessels of kidney.* "The renal artery enters the kidney at the hilus, and divides into branches that pass toward the cortex, then turn over and form incomplete arches in the region between cortex and medulla. From these arches vessels pass to the surface which are called the interlobular arteries; they give off vessels at right angles, which are the afferent vessels of the glomeruli; a glomerulus is made up of capillaries. From each a smaller vessel (the efferent vessel of the glomerulus) passes out, and like a portal vessel on a small scale, breaks up once more into capillaries which ramify between the convoluted tubules. These unite to form veins (interlobular veins) which accompany the interlobular arteries; they pass to venous arches, parallel to, but more complete than, the corresponding arterial arches; they ultimately unite to form the renal vein that leaves the hilus. These veins receive also others which have a stellate arrangement near the capsule (venæ stellulæ). The medulla is supplied by pencils of fine straight arterioles which arise from the arterial arches. They are called arteriæ rectæ. The efferent vessels of the glomeruli nearest the medulla may also break up into similar vessels which are called false arteriæ rectæ. The veins (venæ rectæ) take a similar course and empty themselves into the venous arches. In the boundary zone groups of vasa recta alternate with groups of tubules, and give it a striated appearance."—(Halliburton's *Physiology.*)

9. The *patella* is a flat, triangular bone situated in front of the knee-joint; it is said to be a sesamoid bone developed in the tendon of the quadriceps extensor. Its anterior surface is convex and shows perforations for nutrient vessels; it is separated from the skin by a bursa. Its posterior surface is smooth and oval-shaped, and has two facets separated by a vertical ridge; these facets articulate with the two condyles of the femur. The superior border gives attachment to the rectus and crureus: the lateral borders give attachment to the vastus externus and vastus internus. The apex gives attachment to the ligamentum patellæ. The anterior surface is covered by the tendon of the quadriceps extensor, which is continuous below with the ligamentum patellæ.

10. Sesamoid bones are cartilaginous in early life, but later become osseous. They are developed in the tendons of muscles at points where these latter are exposed to pressure upon the parts over which they glide. Their function is to increase the leverage of the muscles. The largest sesamoid bone in the body is the patella; others are found in or near the joints of the thumb and great toe, in the tendons of the biceps cubiti, peroneus longus, tibialis anticus, and posticus, gastrocnemius, and gluteus maximus.

PHYSIOLOGY AND HYGIENE.

1. LYMPH. *Origin:* There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. *Description:* Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea, fat. *Function:* To provide cells and tissues with materials necessary for their growth, repair, and functional activities; and to receive and carry away their waste products.

2. "The tooth papillæ are all preformed at the time of birth. They remain latent and develop regularly into the different teeth. A serious illness of a child just before their eruption may affect their healthy growth by interfering with proper nutrition, and imperfect and pitted teeth result, which often accounts for an early decay."—(Hill's *Histology.*)

3. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. Their function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

4. Cold weather causes a constriction of the cutaneous arterioles, and this leads to a dilatation of the arterioles of the splanchnic area (which includes the vessels of the kidney). This causes a rise in the capillary pressure of the glomeruli of the kidneys, and the result is an increase in the output of urine.

5. *Insects dangerous to health:* Ants, bedbugs, fleas, flies, mosquitos, sand-flies, tsetse-flies, midges. *To abolish mosquitos*, get rid of all stagnant water, use mosquito netting; *sand-flies* can be exterminated by the use of formalin spray, good floors and walls to houses, removal of all old woodwork, and frequent painting and varnishing of fixtures; *flies* are dealt with by screening, fly papers, disinfectants, and absolute removal of waste material and manure; *bedbugs* require fumigation with formaldehyde or sulphur, absolute cleanliness, pyrethrum powder, and washing floor and wooden bedsteads with emulsion of kerosene oil; for *fleas*, absolute cleanliness.

6. Diminution of the blood supply to muscle results in diminution of muscular activity.

7. "In man, before the consequences of thyroidectomy were known, the whole gland was not infrequently excised for goiter. If the parathyroids happened also to be completely involved in the operation, death quickly followed. But where only the thyroid itself, or the thyroid *plus* the small internal pair of parathyroids, was extirpated, the condition called cachexia strumipriva was observed to supervene. The symptoms resemble those of the disease known as myxedema, in which the characteristic anatomical change is an increase of the connective tissue in and under the true skin. Newly formed connective tissue always contains an excess of mucoids, and for this reason in the early stages of myxedema there is somewhat more than the usual amount of these substances in the subcutaneous tissue. The skin is dry, and the hair falls off. The features are swollen and heavy, the movements clumsy and trembling. As the disease progresses the mental powers deteriorate, too; the patient becomes stupid and slow, and perhaps, at last, imbecile."—(Stewart's *Physiology.*)

8. *Aphasia* is a morbid condition consequent on a cortical or subcortical lesion, whereby speech, writing, or reading may become impaired, either from an inability to coordinate the necessary movements involved in speech or from a defective interpretation of sounds or visual impressions. . . . Speech involves a healthy continuity between the chief motor center in the left inferior frontal lobe and the visual and acoustic centers on the one hand and between the chief motor center and the muscles employed in speech or reading aloud on the other. The centers assigned to speech and writing are motor and sensory, distributed thus: (1) a motor (*glosso-kinesthetic*) speech center, in the third left frontal (Broca's convolution); (2) a motor (*cheiro-kinesthetic*) center for writing, in the posterior part of the second left frontal convolution; (3) sensory centers; (a) *auditory word center*, in the posterior part of the first temporal convolution; (b) the *visual word center*, in the angular gyrus. The motor centers connect with each other and the sensory

centers by commissural fibers. The similar but subordinate centers in the right hemisphere have a limited capacity for taking over the functions of the left centers when these are destroyed.—(Wheeler and Jack's *Handbook of Medicine.*)

9. The acidity of the stomach is maintained by the formation of hydrochloric acid. This may be the result of the action of disodic phosphate on calcium chloride:

$2Na_2HPO_4 + 3CaCl_2 = Ca_3(PO_4)_2 + 4NaCl + 2HCl.$

Or, it may be due to the action of carbonic acid on disodic phosphate, thus:

(*a*) $Na_2HPO_4 + H_2CO_3 = NaH_2PO_4 + NaHCO_3$

(*b*) $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl.$

10. "The blood cell count is readily done with the Thoma-Zeiss hemocytometer which consists of two graduated capillary pipettes, *i.e.* the erythrocytometer and the leucocytometer for counting red and white cells, respectively. The blood is drawn by suction or capillary attraction from the drop obtained by puncture until it reaches the point marked 1, then rapidly wiped dry and the diluent quickly drawn in until it fills the bulb and reaches the mark 101. While drawing in the diluent the pipette is revolved between the finger and the thumb to set in motion the mixing bead contained in the bulb, and when filled again thoroughly shaken and revolved for half a minute. This mixing should be repeated each time before expelling a drop for examination. One has then a mixture, each drop of which presents a blood dilution of 1:100. Many prefer a 1:200 dilution readily obtained by using the mark 0.5 as the upper limit for the indrawn blood. The blood rises quickly if the pipette is perfectly clean and may exceed the proper level if not watched or checked by withdrawing the point and quickly wiping it. If the higher dilution is used any excess is readily blown out or better drawn down by touching the tip with filter paper or blotter. The next step consists in expelling the diluent occupying the capillary portion of the tube, after which a small drop of the mixture in the bulb is placed upon the central disc, the cover glass is placed in position and the cells given time to settle.

The drop should just or very nearly fill the central plateau without running over into the moat around it when the cover glass is applied, else the process must be repeated after thoroughly cleaning and drying the cover glass and counting surface. At the point of contact between the cover glass and the underlying plate concentric color rings should appear indicating perfect contact. Their absence vitiates the count and indicates dust or moisture which must be removed and the process repeated. The specimen being placed under the microscope carrying a Leitz No. 6 objective and a No. 4 ocular, or their approximate equivalents, should show an even distribution of cells throughout both the ruled and unruled fields. Up to this point a certain amount of blood diluted 100 times has been placed upon a field so ruled that each of its squares represents an area of 1/20 x 1 20 mm. *i.e.* each side of the square represents 1 20 mm. A third dimension has been added by the cover glass brought into contact with the blood, but lying 1/10 of a mm. above the level of the depressed central disc which carries the squares upon its surface. One has now to count the number of cells lying within a definite number of the small squares and for the sake of accuracy it is best to include the whole 400, though for ordinary work a less number may be taken if the blood seems to be perfectly distributed. One should pursue a systematic course, crossing from left to right and back from right to left and so on, counting not only the cells that lie within each square, but those that touch its upper and left-hand sides. Having counted the cells, say in 100 squares, one multiples by 4,000 if the original dilution was 1:000, and by 8,000 if it were 1:200, the result representing the number of cells in 1 cm. of the blood under examination. The blood counter must in every case be cleaned immediately after using, (first) with water, (second) alcohol, (third) with ether, and the glass bulb should be absolutely free and movable after the process is completed. If to be again used at once, air should be blown through the tube by means of a hard bulb and rubber tube, not the mouth. The counting chamber should be cleaned with cold water only and should not be exposed to direct sunlight for fear of softening the cement.

The Leucocyte Count.—"For this the large calibered pipette is used with a diluent consisting of an aqueous solution of glacial acetic acid (0.5 per cent.), which leaves visible only the white cells. The most accurate counts are made by using 0.5 rather than 1 as the basis of the dilution, and even this requires a good sized drop. Furthermore, the pipette must be kept nearly horizontal at the time and after the diluent is added, else it will run out of the tube. The diluent is then added to the point 11 and the count can be made with the erythrocyte counting chamber or better with Zappert's chamber in which the central square (one millimeter) is surrounded by 8 unruled squares of the same size. The total obtained by counting the leucocytes in the nine squares is multiplied by 200 and divided by nine, assuming a dilution of 1:200 as above described.

"If the ordinary counting chamber is used, the process is greatly facilitated by inserting an eyepiece diaphragm into the tube of the ocular, which will cut off exactly 100 of the small squares. These may be bought or can be made by the physician from metal or cardboard. The leucocytes in 400 small squares of the erythrocyte chamber may then be rapidly counted and as many additional outside diaphragm fields as are necessary to correct work. Accurate white blood counts require patience and the counting of a large number of fields for a slight error has a disastrous effect. Usually two drops of the 1 10 or four drops of the 1 20 dilution will enable one to count 140-150 cells."—(Greene's *Medical Diagnosis.*)

PATHOLOGY AND BACTERIOLOGY.

1. "*Active hyperemia* may be due either to paresis of the vasoconstrictor nerves or to stimulation of the vasodilators, both of which events cause relaxation of the muscular tissue of the arteries, or to direct weakening or paralysis of the muscular coat of the arteries, as by heat or by trauma. A collateral hyperemia occurs when the blood supply to some other part is diminished. Thus if an artery be blocked, the area supplied by it will be anemic, and around this a zone of hyperemia will for a time be present.

"*Passive hyperemia* or engorgement arises from interference with the venous outflow from a part. This may be due to various factors. The venous circulation is mainly carried on by the contraction of the muscles and by the aspiration toward the thorax which occurs during inspiration. If these forces fail, the blood stagnates in the veins and especially collects in the most dependent parts. The term 'hypostasis' is sometimes erroneously applied to this condition, but should be reserved to indicate the post-mortem gravitation of the blood.

"The causes of general passive hyperemia are enfeebled heart's action and uncompensated valvular disease, of local passive hyperemia, the interposition of an abnormal resistance in the course of the veins; the latter may be caused by external compression, by tumors, by occlusion of the lumen, by growths, thrombosis, contraction of scar tissue, etc., by increased pressure in the abdomen by the pregnant uterus, tumors, and the like.

"If there be free anastomosis in the region supplied by the occluded vein, the hyperemia subsides as soon as the collateral circulation becomes established, but if this does not occur the engorgement will persist, as is the case when such veins as the splenic, the renal, the portal, and the sinuses of the dura mater are occluded."—(Hewlett's *Pathology.*)

2. The lungs are congested and edematous; the kidneys, liver, and spleen are enlarged, congested, soft and pulpy; and cloudy swelling will be found in the secreting glands.

3. The kidneys contain emboli in which may be found bacteria; infarction is present and is observed as a wedge-shaped hemorrhagic area at each point of infection; abscesses are also present.

4. "*Abscess of the liver* is always the consequence of microorganismal infection: the microorganisms are various, and they reach the liver by one of several pathways. The common causative microorganisms are the ordinary staphylococci and streptococci, Ameba coli, Bacillus coli communis, Bacillus pyogenes fœtidus, Bacillus typhosus, Bacillus dysenteriæ, Bacillus pyocyaneus, Diplococcus pneumoniæ, Proteus vulgaris, Actinomyces bovis, etc. The infecting agent or agents may reach the liver directly, as in case of traumatism, or by extension of disease of adjacent organs; or the infection may be carried from afar by the blood stream, that is, by the portal vein, by the hepatic artery, by the hepatic veins, by the biliary ducts, or by the lymphatics."—(Kelly's *Practice of Medicine.*)

5. *Thrombosis of the mesenteric vessels* may be caused by infections, ulcerations, embolism, cirrhosis of the liver, pylephlebitis; it is found most often in anemic and cachectic patients.

6. *Pathology of cystitis:* "The lesions may be catarrhal, suppurative, or ulcerative; unilateral or bilateral; and acute or chronic. In the catarrhal process there is swelling, edema, and congestion of the mucosa, with the excessive formation of mucus; in aggravated cases considerable mucopus or almost pure pus is formed, and there is more or less desquamation and superficial erosion of the epithelium and foci of hemorrhage; or more or less widespread and deep ulceration may occur. In the chronic cases there is, in addition, more or less thickening and pigmentation. Rarely fibrinous exudations or gangrene ensue. There is, as a rule, more or less decomposition of the urine with the precipitation of urates and phosphates. When the infection extends from the renal pelvis to the kidney substance (urogenous pyelonephritis) yellowish purulent streaks are found extending from the papillæ into the medulla and the cortex, and small miliary abscesses throughout the kidney, but most numerous in the cortex just beneath the surface and arranged often in groups. In the event of obstruction in the renal pelvis, the ureter, bladder, or urethra, with consequent increased intrapelvic (renal) pressure, the pelvis and calices become distended, the renal tissue more or less destroyed, and the kidney ultimately converted into an intercommunicating, many-chambered pus sac (pyonephrosis) lined by the remains of the pelvic mucosa; should this become very large, very little kidney tissue may be demonstrable (degeneration, atrophy, and replacement by connective tissue)."—(Kelly's *Practice of Medicine.*)

7. *Elephantiasis* is the hypertrophic condition of the skin and underlying tissue, having its origin in lymphatic obstruction and characterized by edema, enlargement, thickening of the skin, overgrowth of the papillæ, and pigmentation. The causal lymphatic obstruction may be due to tumors, cicatrices, erysipelas, and the *Filaria sanguinis hominis.* It is most common in the tropics and is most often observed in male adults. The structural changes incident to the disease are hypertrophy of the entire skin and subcutaneous tissue, edema of affected structures, and dilatation of the blood-vessels and lymphatics with inflammation of the latter. The disease usually affects the leg and foot but the genitalia may be attacked.—(Hughes' *Practice of Medicine.*)

8. In *myelogenous leukemia* the red blood cells are greatly diminished, the hemoglobin is also diminished, normoblasts and megaloblasts are present. The leucocytes are enormously increased in number, there may be 300,000 to the cubic millimeter instead of 10,000 or 12,000 as is normally the case; mast-cells are present, and myelocytes are found in large numbers. The proportion of polynuclears is not disturbed.

9. *Pathology of malaria:* "During the paroxysms, the principal changes are: (1) Enlargement of the spleen, sometimes very great. In recent cases the organ is soft; in older cases firm ('ague cake'); (2) Enlargement and congestion of the liver; (3) Congestion of the bone marrow, the brain and meninges, and the kidneys. In all these organs the vessels are full of plasmodia and of melanin. There is also present a yellow pigment, not confined to the vessels, which consists of altered hemoglobin. Marked diminution of the number of red cells, and pigmentation of the leucocytes, are conspicuous features. The lymphocytes are also relatively increased for some time after the paroxysm, but leucopenia, not leucocytosis, is a feature of malaria. In malarial cachexia the spleen is not necessarily pigmented. The enlargement is mainly due to thickening of the capsule and trabeculæ, and the organ is hard. The liver is frequently enlarged. Anemia is a conspicuous feature."—(Wheeler and Jack's *Practice of Medicine.*)

10. "*Necator americanus*, the New World hookworm, is a cylindrical worm, 5 to 11 mm. long, and is possessed of a dorsal and a ventral pair of lips at the mouth, a prominent dorsomedian buccal tooth, and four buccal lancets; in the male the dorsal ray of the bursa divides at the base and each branch possesses two tips; in the female the vulva is the anterior half of the body; the eggs are thin shelled, 64 to 72μ long, by 36 to 40μ broad; they are oval with somewhat bluntly rounded poles."—(Kelly's *Practice of Medicine.*)

(To be continued.)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PROGRESSIVE MEDICINE. Edited by HOBART ARMORY HARE, M.D., assisted by LEIGHTON F. APPLEMAN, M.D. Published by Lea & Febiger, Philadelphia and New York. Volume XVII, No. 3, whole number 67; 307 pages. Subscription price, $6.00 per annum.

CANE SUGAR AND HEART DISEASE. By ARTHUR GOULSTON, M.A., M.D. Published by Paul B. Hoeber, 67 and 69 East Fifty-ninth Street, City; 107 pages; $2.00 net.

ON PHARMACO-THERAPY AND PREVENTIVE INOCULATION. By SIR ALMROTH E. WRIGHT, M.D., F.R.S. Published by Paul B. Hoeber, 69 East Fifty-ninth Street, City; 124 pages. Price, $2.00 net.

DISEASES OF THE NERVOUS SYSTEM. By SMITH ELY JELLIFFE, M.D., and WILLIAM A. WHITE, M.D. Published by Lea & Febiger, Philadelphia and New York. Illustrated with 331 engravings and 11 plates; 796 pages.

TREBALLS DE LA SOCIETAT DE BIOLOGIA, Any Segon, 1914. Publicats Sota La Direccio de A. PI SUNER. Institut D'Estudis Catalans, Palau de la Diputacio, Barcelona; 279 pages; 10 ptes.

PHYSICAL DIAGNOSIS. By RICHARD C. CABOT. Published by William Wood & Company, sixth edition, revised and enlarged, with six plates and 268 figures in the text; 521 pages. Price, $3.25 net.

MILITÄR-PSYCHIATRISCHE BEOBACHTUNGEN UND ERFAHRUNGEN. Von Stabsarzt Dr. WEYERT. Published by Carl Marhold Verlagsbuchhandlung, Halle, a. S. 145 pages. Price, M. 3.60; per volume of 8 parts, 8 Marks.

THE OPHTHALMIC YEAR-BOOK. Vol. XI. Edited by EDWARD JACKSON, M.D., Sc.D. Published by Herrick Book and Stationery Company, Denver, Colo. Illustrated; 545 pages.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U. S. Army. Second Series, Vol. XX. V.—Water Works. Published by the Government Printing Office, Washington; 595 pages.

QUIZ-COMPENDS, ANATOMY. Eighth Edition. By Dr. POTTER. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia. Revised by D. GREGG METHENY, with 139 illustrations; also numerous tables and 16 plates of the arteries and nerves; 428 pages. Price, $1.00 net.

MARIE TARNOWSKA. By A. VIVANTI CHARTRES. Published by the Century Co., 353 Fourth Avenue, New York City; 305 pages. Price, $1.50 net.

THE MEDICAL CLINICS OF CHICAGO. September, 1915, Vol. 1, No. 2. Published by W. B. Saunders Company, Philadelphia & London. Published Bi-Monthly. Octavo of 194 pages; 44 illustrations. Price, per year, paper, $8.00; cloth, $12.00.

WHAT TO EAT AND WHY. By G. CARROLL SMITH, M.D., of Boston, Mass. Second edition, thoroughly revised. Octavo of 377 pages. Published by W. B. Saunders Company, Philadelphia and London. Price, cloth, $2.50 net.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS. By JAY FRANK SCHAMBERG, M.D., Professor of Dermatology and Infectious Eruptive Diseases. Third edition, revised. Published by W. B. Saunders Company, Philadelphia and London. Octavo of 585 pages; 248 illustrations. Price, cloth, $3.00 net.

NURSING IN DISEASES OF THE EYE, EAR, NOSE AND THROAT. By the Committee on Nurses of the Manhattan Eye, Ear and Throat Hospital. Published by W. B. Saunders Company, Philadelphia and London. Second edition, thoroughly revised; 12mo volume of 291 pages; illustrated. Price, cloth, $1 50 net.

THE CRIMINAL IMBECILE. By HENRY HERBERT GODDARD. Published by The MacMillan Company, New York; 157 pages.

DISEASES OF THE NOSE AND THROAT. By ALGERNON COOLIDGE, M.D. Published by W. B. Saunders Company, Philadelphia and London; 12mo of 360 pages; illustrated. Price, cloth, $1.50 net.

BLOOD PRESSURE IN GENERAL PRACTICE. By PERCIVAL NICHOLSON, M.D. Published by J. B. Lippincott Company, Philadelphia and London. With eight illustrations, third edition; 179 pages.

HABIT AND MALOCCLUSION.*

BY GEORGE VAN NESS DEARBORN, M.D.,

CAMBRIDGE, MASS.

PSYCHOLOGIST AND PHYSIOLOGIST TO THE FORSYTH DENTAL INFIRMARY FOR CHILDREN, BOSTON.

My remarks will concern certain features of the theory of habit so far as related to special forms of muscular behavior. The precise name of the discussion is "Habit and Malocclusion." It is a great satisfaction to me to have a chance to talk to you. I talk four days a week to over five hundred students, male and female, and they have me so thoroughly in the habit of talking that it has become a pleasure! My scientific specialty being other than dentistry, it rightly may be assumed that my remarks will concern habits mostly, rather than malocclusion. However, unless there be a preclusion, near the conclusion of my talk there will be some little inclusion of occlusion.

Habituation is a well-nigh universal process in our experience. The over-eating habit, for example, just exemplified. Machines made of steel, of brass and of wood are said by some to acquire habits just as organisms do. Shoes, coats, neckscarfs, have habits. The rain running down a new mountain side soon acquires definite habits which we call brooks. You have all experienced, probably, habits in dental engines, not, however, worse or better than your own habits. Every machine, in short almost everything we are familiar with, has habits. Habit is surely a universal process in matter, in all material mechanisms, whether non-living or self-repairing, *i.e.* living. But observe that in organisms its basis is in the *matter*, not in the mind, so far as we can see. A "mental habit" at present means practically nothing. Compare, for example, if you wish to understand how habit in living "mechanism" is determined by the material aspect and not by the mental, the shadows on the moving-picture screen. It is impossible to think a series of successive mere shadows as having any habits; they are obviously put there by material mechanisms from outside themselves; it is as impossible to think of habit in such a series itself as it is to think of the events as the respective causes of each other. If we are to find anything, then, in the way of causation of habit in this pure series of events or processes, we have to turn back to the mechanism that continues it, namely, the film apparatus. It is more or less the same with mental process, viewed as phenomena. It is at present unbelievable that habit in an organism is a mental process. It is matter, protoplasm, that has habit. The mind doubtless exists in some mode separate from the body, but if so we know nothing of it as yet, and, therefore, habit (to conclude this matter) appears to me to be a matter of mechanism and not of the soul at all.

However that may be, a polemic question certainly, habit in our organisms and personalities is practically universal. The only exception of which I am aware is the lack of a habit not to form habits! It has been said that habit is "second nature," but William James, the great dead psychologist, suggests that habit is nature itself. In order to realize how universal the process is in organisms, it is necessary for a moment to point out the nature of the only sort of process that is *not* habitual, which is, namely, true or real voluntary movement. Suppose, for example, that your revered and philosophic grandmother, having much money to spend, had said that she would give you a thousand dollars if you, without training, would engrave *without any slip or mistake whatever* a complex, delicate, and artistic monogram on the rounded belly of a small cream jug. Those of you who have tried to do such a thing realize the difficulty of accomplishing it, the difficulty, clearly, being not one of doing it, in a sense, but one of *preventing* yourself from doing something you did not wish to do. In short, it is the *inhibitory* process, which is the really voluntary movement. I take it that this is the only occurrence in all the body's behavior that is not somewhat habitual, and that everything else you could possibly think of has some degree or other of habituation in it. It is in all cases relatively easy and in some extremely easy to do things "never done before" because they all have some degree of habituation, for this, in short, is the universal principle of neuro-musculo-glandular action. So you have in the organism all possible grades of habituation, from the strictly new voluntary movement to the action of the heart or the beating of any other of the rhythmic organs. But inhibition is theoretically the sole unhabituated, and represents the free will of the human as opposed to the vegetative.

Next we will take up briefly the biologic function of habit, and this, as you all know, is economy; first, of time, second, of energy, and third, economy of variation. Habit serves, at least in the way of economy, those three things: it saves time, saves unnecessary expenditure of energy, and makes everything more constant. Habits then are theoretically sure to be "bad" as well as "good," and some of them indeed are bad and surely some are good. Some suspect that bad habits are formed more easily than good habits, for fish, as well as souls, bite averagely well on the Sabbath day. The basis of the fact that it is easy to form habits, especially bad habits, in the long run is always *satisfaction* in some way or in some other. We always get

*Remarks made (for the most part) before the Eastern Association of the Graduates of the Angle School of Orthodontia at Hotel Puritan, Boston, 27 March, 1915.

satisfaction, of course, out of the repetition of an act which causes any degree of pleasure, but also out of pain, ideational satisfactions, or out of any other form of will-fulfillment whatever, we may get at times true satisfaction. You all know, for example, that when one has a sore tooth there is a kind of satisfaction to be obtained from pressing that tooth, making it hurt; if you have a hang-nail there is a certain sort of satisfaction in causing pain from it. Thus we cannot say that the formation of habit depends only on true pleasure, because there may be no pleasure concerned. The same applies to self-denial, and to other forms of satisfaction-getting, which appear to be so painful. Even the martyr being burned at the stake can be psychologically said to get some compensatory satisfaction out of what is usually considered an ualloyedly agonizing process.

Often the satisfaction concerned is subtle and hard to appreciate, and yet it is none the less effective. In other words, it may be purely physiological, kinesthetic, or tactile. A neuromuscular habit may be purely kinesthetic, or it may be a matter of satisfaction derived from the pure sensory experience of touching things, perhaps the result of an instinct of curiosity of an exploratory nature. The dynamic basis of the satisfaction, as of joy, is the kinesthesia of normal bodily activity becoming more and more inhibitory (human) as the child's personality unrolls. A child may do things which promptly lead to fixed habits with any one of these three physiological suggestions, so to say, behind the movements. Action itself is seen to be satisfaction in this way, and muscle-action, at first made by chance, so to say (really developmental practice), may become quickly and fixedly habitual by repetition long before any habit is realized.

It has been said that the bodily mechanical movements of respiration, the ordinary processes of inspiration, and to a less extent of expiration, give rise on the average to more satisfaction during a life time than any other thing—the kinesthetic experience of taking air into the lungs. I merely wish to suggest here, for future reference, that this universally known process of inspiration pneumatically considered is one especially of suction.

Cosmetic values, of course, are very greatly disturbed by some of the muscular habits that children get into. If we compare the women with the children who sit before us in the trolley cars, for example, in this respect, we can see the effects ahead as well as the causes behind. You can readily point out certain children who, when they become adults, will have badly deformed and perhaps unworthy faces simply because they have been allowed to form the habit of holding their mouths, and so on, in various postures which are going to become fixed. How many good men are needlessly scared away from matrimony by this contrast between the middle-aged women whom they sometimes see and these women's children! Physical education should care for these conditions. As I pointed out some years ago, in the child's early years it should be one function of the physical educator, in the playgrounds and in the schools, to tell children what some of them are doing in this particular respect, and to point out some of the deformities which they quite needlessly are bringing on themselves by a lack of appreciation of what is happening through, in turn, a lack of proper guidance. This certainly should be one of the recognized and practised functions of physical instructors on the playgrounds and generally in the schools. Physical education, I regret to say, is certainly not making many important applications in these broad outside ways.

Human personality has two phases: one is actuating, impulsive, "vegetative," and the other is inhibitory, restraining, or controlling, and comes from the cortex of the brain. Childhood inherently lacks this latter inhibitory phase of behavior, and its necessary development can occur only through the endless action of every possible group and combination of muscles, nerves, and glands. The nerve-centers have to be impressed year after year with what James called the motor ideas of every possible action that the organism can make. Biologically, then, childhood is inherently the time of impression of the nerve-centers (especially the cortex of the brain and spinal gray matter) with all possible movements. Childhood is the period, too, of growth and development by way of practice and habituation. By these and such means Nature incites evolution, especially by the dim satisfaction of new kinesthetic expressions.

This kinesthetic matter is, of course, by no means a new matter, but only in recent years has it been appreciated as the fundamental sense of the animal, especially of the human animal. Curiously enough, there is something about the sense of vision that entirely drowns out "the muscle-joint sense," but this is only a matter of consciousness, for the kinesthesia is there all the time and in absolute control of the muscles. We do not control the muscles by means of vision; our eyes only stop and start each gross movement about where it should be stopped or started, for it is the kinesthetic sense that has the effective control in all ways over the muscles. This sense is dim but it is continual, and when the eyes are closed so that we can get consciousness behind the subconscious, so to say, it can be developed almost to any extent. Helen Keller, for example, in her book, "The World I Live In," has a whole chapter devoted to telling how much benefit she gets out of the kinesthetic sense and her other remaining senses.

At this late day in the psychology of behavior, we do not need to spend much time in the discussion of kinesthesia. It is a sense often subconscious which originates in the joints, muscles, bones, tendons, and skin; all of these parts, at least, are continually sending strains or impulses into the cortex of the brain. Only so has the brain complete control of the organism, just as it would be impossible for the switchmen in the tower down at the South Station to guide the numerous trains out and in that station unless he knew continually where each train was, its speed, and so on. That corresponds to the kinesthetic impulses from all parts of the body, giving information as to the exact posture and location of the various limbs and the degree of contraction of all the body's muscles.

The kinesthetic sense, therefore, is there at the same time in complete control and under complete control, and the voluntary muscles are actuated consciously by the child because of the satisfaction it affords, if for no more explicit reason. Sometimes the need of relief from kinesthetic strain (allied to the "fidgets" coming from too much caffiein or nicotin) is the cause of apparently random and seemingly unnecessary muscular movements. On a Sunday afternoon when we have not

had our usual muscular activity we get "fidgety," *i. e.* the muscles get uneasy as the result of their demand for adequate activity, and this need shows itself sometimes as positive unpleasantness. Of course the child has this need even more distinct than has the adult, and it urges him on continually to instinctive movements of many kinds; yawning is a good illustration of a reflex endeavor to relieve this hyperkinesthetic strain.

Physiologically we may think of a motor habit (and probably all habits) as a set of kinesthetic impulses or strains, passing from the parts most concerned into the great cortex. When these strains have continued relatively long without much variation, in some way as yet wholly indefinable, they impress the central nervous system, probably the extremely sensitive and delicate neurones of the cortex in particular, and tend *pro tanta* to dominate behavior. It is worth noting (and, so far as I know, it has not been noted adequately heretofore) that it is not that the formation of a motor habit is a pleasant process or one that gives obvious distinct satisfaction, but, on the other hand, that opposition to the habit gives distinct unpleasantness, often of an acute kind. How extremely unpleasant, for example, it is not to frighten away a fly lit on the tip of one's nose. Here is inhibitory kinesthesia hard to ignore! It would be more accurately scientific to say that the formation gives pleasantness which is, however, largely or wholly subconscious, while opposition to the habitual kinesthetic set causes conscious unpleasantness. A theoretic pessimist might argue pessimism from this: The formation of habits gives us no pleasure, but to break them is pain. "Facile est descensus Averni, sed ——," etc. Many habits, of course, have extraneous pleasure connected with their formation, but intrinsically the process seems regularly to be a subconscious one. As I have elsewhere shown, the actuating phase of kinesthesia is subconscious. On the other hand, the inhibitory kinesthetic strains or impulses are conscious, and when violently opposed may be intensely unpleasant. When the case is one of breaking a habit the unpleasantness may be so great that in practice it dominates the behavior at the time, and oftentimes of course subconsciously, if not deliberately in consciousness, influences the mind of the individual strongly enough to become a permanent motive, preventing the breaking of the habit. Here, then, we see the pure science of the principle, which amounts to a rule of practice, for the overcoming of bad motor habits, especially in older children, to which we shall recur later on: *Do not attempt* to break a habit in a bold and direct way; always try to be rid of it by replacing it with another habit quite as persuasive physiologically and mentally, and not injurious. In this way the individual is given whatever of satisfaction or of pleasantness (not to say, sometimes, actual pleasure) accompanies the formation of a habit while, on the other hand, the inhibitory unpleasant kinesthesia is kept at a minimum, the contest being thus a purely neural and physiologic battle, little concerned with the conscious will of the individual, and thus economical.

So much for a few obvious points in the physiology and psychology underlying habit-formation and habit-breaking in general.

We are going to discuss, of course, only certain arbitrary types of habits. In practice, that is in reality, the "types" are indefiniably confused and usually far more complex than may be described here. The essence of human personality is its uniqueness, and the chief reason for our scientific interest in behavior lies in this continual uniqueness of the individual, a law unto himself and not to be discussed in detail under any circumstances.

I have tried to suggest that the reason for some habits is the kinesthetic satisfaction, continual, however slight, obtained from normal muscular actions. So far now as malocclusion is concerned, more or less arbitrarily we may consider four groups of kinesthetic habits especially, which lead to deformities of the mouth and of the dentition. In the first class we have the group which we may characterize as sucking and biting movements, which involve the sucking of the thumb and fingers, fist, either lip, the tongue, or the clothing. Some of the worst cases of paradontic deformity come from the rather common habit of biting the clothing; boys especially get in the habit when young of biting the clothes and tugging on them. Perhaps more practically important than this, because commoner, is the use of the so-called "pacifiers," which really should be called something else, even defacifiers. A second group of actions is the biting habits, biting either lip, the tongue, or hands. Biting is a well-defined instinctive movement in most young mammals. Third, a group which requires less effort than the other two, namely, mouth-breathing; one of the commonest, I take it, of the causes of malocclusion. It appears to be always forced by a respiratory obstruction, for no one, as far as I have observed, breathes through the mouth purely from physiologic choice. The passage of air through the nose is normally, at least, as easy as it is through the mouth, so that, as I have just said, no one with entirely unobstructed posterior nares breathes through the mouth. The fourth class of paradontic habits includes a very large number of arbitrary actions, including those of the busy hands in relation to the mouth, all sorts of tractions, distentions, etc., habits of many kinds that young children and sometimes older children get into, of handling their mouths in many various ways. I do not need to do more than cite the numerous other causes of malocclusion with which you are familiar, but there are at least thirty-five conditions which have been mentioned by witnesses as causes of this kind of deformity. Rickets is one, and osteomalacia, and tuberculosis, syphilis, scarlatina, measles; pathological injuries of various kinds coming from these organic disasters. Then there is the group of popular acquired diseases such as adenoids, enlarged tonsils, chronic rhinitis, and deviated septum. Then there is a class of congenital deformities: cleft palate, harelip, supernumerary teeth, infranumerary teeth, hypertrophied tongue (such as we see in cretinism), atrophied tongue, abnormal frenum, and other forms of maldevelopment. Early loss of the decidious teeth, early loss of the permanent teeth, and late development of the permanent teeth, complete what, I think, is a fairly complete list of paradontic occasions or causes to be found in the literature of malocclusion.

Of all these habitual occasions of malocclusion I have no doubt that sucking, the first one mentioned, is of most theoretical interest; first, because it is the most common, and second, because it is most widely involved with the depths of human nature. Sucking and biting, I do not need to

suggest, may be seen well in most all young brute animals and may be seen particularly well in pups, in many respects like children. The sexual relations of sucking have been much discussed of late. The great Freud has made some revolutionary and sensational suggestions in regard to it, and one in particular, that this is one of Nature's means of bridging the sexual instinct from one generation to the next; he holds the opinion that the sucking of anything affords sexual satisfaction, more or less. I think it is generally admitted now by most neurologists that Freud's opinions regarding sexual matters, of which this is an example, are in places exaggerated. To the maternal suckee, so to say, often there is some or even great satisfaction, but it is hard to see that there is much satisfaction to the sucker, unless the process produces something worth while, as, for example, milk or tobacco smoke! However, in what way the young infant can get into the habit of sucking the thumb, as very many infants do, except on the basis of kinesthetic satisfaction, I am unable to understand unless indeed it be true, as Freud claims, that there really is in it a dim, subconscious sexual satisfaction. But Freud has certainly exaggerated the universality of sexual effectiveness in childhood, whether this be true of sexuality in adult life or not. It certainly is not *necessary*, as we have seen, to bring in sexuality to account for the widespread satisfaction of sucking and biting. Of course a man sucking a cigar has nothing whatever suggesting sexual reference, and the erethistic young man, if anyone, would have it. In children who are sexually precocious (from a deficiency of product of the pineal gland or deficiency of the product of the pituitary body?) and in highly stimulated, unrested children, sucking expressions, it may be, are actually carried over from the mother's breast and nipple to their own potential sexual feelings, but not normally, to any effective degree, I am sure. The widespread muscular (kinesthetic) satisfaction of sucking seems adequate then to explain its great popularity at all ages, but this doubtless merges in the abnormally erethistic and sexually precocious into a true sexual satisfaction, especially, perhaps, in boys. Ellis and Moll explain these relations in an adequate degree.

A well-known New York writer on orthodontia (whose name has escaped me) has offered as an explanation of thumb-sucking that the movement of the tip of the tongue in the process stimulates the chorda-tympani nerve and thence, through the pneumogastric's cardiac branch, increases the heart's action, resulting in increased blood supply to the brain, thereby increasing the circulation of the blood to the brain and inducing a sensation of satisfaction to the child. He illustrates this by the experiment of drinking a glass of water: if the water be swallowed in one gulp it produces only a slight increase of the pulse, but if it is slowly sipped the pulse is greatly augmented. As a physiological problem this, like a million others yet unsolved, is interesting, very, but cerebral congestion does not seem regularly to enhance euphoria, and besides it is such a long way around. It is almost as far-fetched as are some of Dr. Kirk's explanations of caries.

Whatever may be the cause of this habit (and that is a matter of academic discussion of purely theoretic interest), sucking and biting, we may conclude, are almost an innate impulse in humans as in brutes and are continued from infancy on, and become continuous on the basis of kinesthetic satisfaction when no other satisfaction helps. This is, as near as I can make out, the philosophy of sucking. The precise mechanics of the malocclusional deformity itself I need not discuss, because you know and understand it better than I do.

But three basal principles need to be recalled for the understanding of the often shocking effects of sucking the objects we have mentioned above and others during the first eight years of life; mere mention and not elaboration of these conditions is necessary. The first principle to be kept in mind is the great plasticity of the jaws, especially in babies. This is something I do not need to suggest any further to experienced gentlemen of your profession; but, curiously enough, students do not understand it, but they think of bone as something inherently hard, and more or less unplastic and fixed; but, of course, quite the contrary is true. The bones are extremely plastic, colloidal in nature, and subject to almost any amount of deformity from long-continued impacts and strains. As an example to illustrate this, you sometimes may see a delicate green herb pushing its way through an asphalt pavement. The sprig may be so frail that it could be easily broken with the finger, but it may push its way through a concrete pavement if the light conditions are right, by its low but continuous pressure on what is really a fluid medium. So with the jaws.

The second principle is the vigor and power of the respiratory and inspiratory movements, even in babies. If you wish an example of this, note the enormous cries of some minute and very young infants. It seems sometimes as if the cry were inversely in proportion to the size of the baby, and we sometimes are tempted to ask where they can possibly keep all that sound. Of course lung power is one of the most conspicuous things in the infant, and it has to be exercised in all kinds of ways, and here much muscle is involved.

The third consideration necessary to account for deformity is that long periods of continual pressure are involved, and the frequent repetition of the acts, as in the case of the sucking process. "Pacifiers," bad as they are, are not so bad in some respects as certain other means used by some thoughtless or vicious nurses for the same purpose, but occasionally the results are certainly far more disastrous in infancy. Biting the tongue, either lip, or the hands are conditions in part like those of sucking, but in part also the deformity in this case comes from unilateral continual pressure of one kind or another. Mouth-breathing (due to nasal or pharyngeal obstruction and made worse by tonsilar hypertrophy) is now not so common as formerly, before it was customary to keep adenoids out of the pharynx.

A fourth and last principle underlying paradontia includes the fact of arbitrary postures of the mouth and of the hands (such as the common dragging on the lower jaw), which are innumerable and undescribed and do not need to be further discussed. These represent habits theoretically as "pure" as any we could find, because we know that there is always at least a dim satisfaction coming from such muscular actions. These habits often start by chance, but are continued by this complex and overmastering power of habituation, and soon become fixed just as firmly as the shape of an old deformed bone, or any other part of the organism as it grows and hardens.

Modern medicine is inherently and ever more *prophylactic;* it is the *duty* of the dentist, the nursery maid, the physical educator, and the parent to *prevent the formation* of malocclusional habits. To this end the surest road in the long run, it seems to me, is vigorous biological normality, busy normality, I have called it. Try to make the child normal by natural hygienic means, and keep him usefully busy with natural out-of-door muscular distractions, for this kind of fatigue leads to much sleep, sound and deep, that may be called out-of-door sleep, whether indoors or out. Anything which tends to nourish the nerve-centers will tend to lessen all those tendencies toward habitual exaggeration of any one movement or kind of movement. The old verse of our dear old grandmothers, "And Satan will find mischief still for idle hands to do," is as true of babies as of older folks, and as true of lips and tongues and diaphragms and pterygoids as it is of the hands.

Modern systems of elementary education, those, for example, of Seguin, Fröbel, Montessori, Witte, Sidis, Stoner, Berle, and others, plus adequate playground systems, are doing much and are going to do much more toward developing this *busy normality* in the child. I have great respect and hopefulness for the great new system of playground education, municipal playgrounds conducted by trained experts; there is no assignable limit for the good that playgrounds so conducted can do for children, especially in the cities. The system teaches them perhaps, for the first time, self-respect, shows them their capabilities that often would be developed in no other way. Above all, there is in the system no end of opportunity for instruction of the most advanced, most useful, and yet of the simplest kind. One of my pet hobbies is that many useful, and indeed vastly important things, which children are perfectly competent to receive greatly to their future benefit are kept away from them unjustly on the mistaken supposition that their minds are not far enough advanced to receive them. The young child of average intelligence, you may be certain, can be told many things of the most fundamental importance to their complex human lives, provided the teller knows how to do it. The impression on the subconscious mind made early in such a way may be effective throughout the life of the individual; the wisdom of life especially. What a shameful waste not to inform the child how to live, so that the crises of life, especially the emotional life, may be anticipated to some extent and sad experientia be not their only teacher!

Every intelligent child would be interested, for example, in the theory of habit; it is a matter of universal interest. If you explain to the child of average intelligence, even if he forgets in half an hour, the universality and the force of the principle of habituation, the subconscious impression made upon him will serve as a more or less unconscious rule of behavior whether he thinks of it consciously or not. This is one of the points I have in mind in speaking of the intelligent education of these patients. *Explaining* things to them—is the simple enough principle of modern psycho-therapeutics—full explanation and, to some extent, sanction of the habit. A child should not be punished or abused because he has a habit, but he must be led to *understand* the human nature of it and must be able to work out his own gradual cure. No other method is scientific, no easier way is sane or safe to the delicate personality of the young child, as we shall explain more fully shortly. For the general practitioner of the dental or other specialty of medicine, serving an office practice, this makes, in slang terms, a hard proposition. Such habits are more readily prevented than safely checked.

You cannot do much in practice unless it is in your own household, or unless you can deeply convince the parents of the essential importance of rightly controlling the habit, and obtain their full and active cooperation. In many cases at least, however, it is certain that if you start far enough back, by giving a course of out-of-door hygiene, getting them to go "back to the farm" for several months, six or so, and so fundamentally to equalize and invigorate the nervous system, thus making it so active and vigorous that this particular neuromuscular action will be practically swamped out, you may get results. I certainly would not try to "break" a habit as such; but it may be safely and surely, most often, bent and persuaded out of its wrong growth.

The educational system, it seems to me, is *inherently defective,* in that professionally it is not based on a modern knowledge of child-life nor on the nature of the neuromuscular mechanism. One thing in particular that we need to get out of our teachers' consciousness, is that children are "little men and women." They are, of course, just as different from men and women almost as can be, and different in the most fundamental respects. One of the chief practical difficulties in a general reform of this matter is clearly there are far too many children to the teacher. The public has not realized yet what a good *financial* investment education is, and the taxpayers do not spend one-third as much as they should on it; they should spend four times as much as they do now, and have classes of fifteen pupils instead of from thirty to sixty, and then have the teachers properly "fitted"; professional teachers instead of girls waiting for husbands to appear at papa's front door. All the intensive modes of education mentioned are making a start in the right direction, but see what a long road this is!

The breaking of a well-fixed psychomotor habit (as has been anticipated) is wholly, for the most part, unjustifiable. A habit is not like a femur bone which may be forcibly broken and in time made to grow again straight, but, on the other hand, habit is a part of the child's organism, part of his brain action and his muscle action, ingrained in every portion of the mind and body. Too much shock to such a mechanism when young deranges it and may set up very serious undercurrents in the nervous system. As you are doubtless aware, from 60 to 70 per cent. at least of chorea cases are known to start in some sort of nervous shock, usually fright, and it is obvious that an acute form of shock might come from the strict, absolute insistence that a child should not continue certain deeply ingrained habits. It is not safe to break, in that literal sense, those neuromuscular habits; too much shock in such a mechanism deranges it; one stops any child-activity at one's peril, unless it be done along natural methods.

The theoretic cure of a bad habit is a threefold process of (1) normalizing, (2) displacement (substitution), plus (3) enlightenment, the purpose being displacement. The normal way of breaking a habit, the safe way, is to displace it with some-

thing else. The neuromuscular mechanism is far too subtle and sensitive a thing, and these involuntry habits involve too much of a strain, to make it safe to insist that it be broken off short, so to speak. Enlightenment is the crying need of the times, in matters of diet, sex, and how to live in general, and education so far has neglected them. I think the average normal child can be more or less controlled by way of his own interest; and, as I have already said, I believe that the average child even as young as five or six years, can be guided wisely if properly approached along the lines of psychotherapeutics, careful, elaborate explanation adapted to his years, pointing out the really fundamental things. I think a child under such instruction, when it is expedient, can be impressed, or at least his subconscious mind can be impressed, so that it would be effective in many of these habit conditions. But one must start with a normal, that is an out-door, nervous system and musculature.

"Back to the farm!" is one of the most prominent "slogans" of the day. To my mind one of the greatest problems of our crowded civilization is how to get people, when they have children to raise, to go back to the farm, out into the country where there is absolute necessity of building up a neuro-musculo-glandular system which will not allow itself to be beguiled into one-sidedness, into bad habits unworthy the independence of human womanhood and manhood.

Out-of-door exercise and plenty of sleep—that is the dual but shortest road to a strong nervous system. Than to live in some place or in some way so that these are amply available, I do not know any other certain way; in fact I would suggest in every case of bad paradontic or other bad habit that we should urge on the parents the absolute necessity of the victim getting a long and real vaction in the real country. I believe that ordinarily that will have more immediate benefit than anything else they could do, and be wholly safe and hygienic, and as speedy, too, in its action as the conditions of organic life allow.

A change of location and of surroundings assists in breaking up habits in so far as the changes invigorate the organism. When you travel in Europe, hoping to get away from your worries, you hardly succeed in leaving them behind, but in so far as travel or change invigorates, as it often does, I should say that it would lessen all abnormal functional conditions, these malocclusional habits among the rest.

Unless you have had much personal experience and unless you have thought about these habits as found in even the average child, you are not apt to realize how very firmly fixed they become. The most trivial habit soon becomes implanted so that it is *a part of the organism* even in normal individuals, and where there is any lack of inhibitory control, in a child, notably, who is slightly defective, it will become in the most literal and most obvious sense a part of the organism. This is a physiological process, the means to economy taken by the nervous system in the youthful individual. There is a very elaborate inhibitory mechanism in the individual after adolescence, throughout the upper part of the cortex of the brain, if not in the cord and stem, and that is the normal road by which to go after these habits rather than any means which would involve breaking them off short. Restraint and guidance from the neopallium, the upper layers of the cortex cerebri, inhibition through guidance, rather than trauma leading to something akin to paralysis! It may be a long-long way to this particular Tipperary, this education as to how to live, but it is the road that we all desire to see worn hard and smooth at once by the world's ever-hastening feet. The really *right* road, the ultimate golden street of all, is Prevention Way, narrow but straight, leading directly to the heaven of Normal Humanity, victim only of its own deliberate faults.

COMPARATIVE MORTALITY EXPERIENCE AMONG ABSTAINERS AND NON-ABSTAINERS FROM ALCOHOL.*

By WILLIAM EVELYN PORTER, M.D.,

NEW YORK,

MEDICAL DIRECTOR OF THE MUTUAL LIFE INSURANCE CO. OF N. Y. PRESIDENT OF THE ASSOCIATION OF LIFE INSURANCE MEDICAL DIRECTORS OF AMERICA.

DURING no period in the history of the world has the question of the effects of alcohol been so generally considered by all classes of people as during the past year. The rulers of most of the great nations, statesmen, commanders of the army and navy, scientists and philanthropists have all given it serious consideration and study. Statisticians have aided with the work, but unfortunately the Medico-Actuarial Committee were unable to include in their presentation material which would, undoubtedly, have furnished the most accurate scientific data bearing upon this important subject.

As the Mutual Life Insurance Company of New York, through its able Actuary, Mr. Emory McClintock, was the first company in the United States to present statistics of definite value on the subject, it seemed appropriate at this time to present the latest experience of the same company, calculated and tabulated along the lines followed by the Medico-Actuarial Committee in their report. Although the volume of material is not large, care has been taken to make it homogeneous and as free as possible from sources of error likely to affect its scientific value. To eliminate conflicting elements, manifest as a result of habitat, the consideration, confined to domestic males, eliminated those residing in South Carolina, Georgia, Florida, Mississippi, Arkansas, Louisiana, Oklahoma, and Texas. To avoid the errors due to the influence of certain occupations, it has been divided for study into five occupation classes having the largest number of entrants, as follows:

TABLE A.—ISSUE OF 1907-1912. DOMESTIC MALES

Class	Occupation	Insured		Per Cent. of Total Entrants	
		No.	Amount	No.	Amount
224	Indoor clerical service	15,402	$27,522,750	9 3	5 9
226	Merchants and dealers	22,379	76,704,200	13 6	16 6
229	Salesmen (not in liquor business)	13,132	24,495,225	8 0	5 3
233	Farmers	27,859	50,569,450	16 9	10 9
240	Factories and mills proprietors, managers and superintendents	5,824	33,475,825	3 5	7.2
	Total	84,596	$212,767,450	51 3	45.9

These five classes constitute about one-half of the total number of entrants and are divided into three

*Read at the twenty-sixth annual meeting of the Association of Life Insurance Medical Directors of America, Oct. 14, 1915.

groups, namely: (1) Total Abstainers; (2) Temperate (occasional but not daily users); and (3) Moderate (steady, free, though not excessive users).

I will next present Table "B" containing the five occupation classes referred to, that each may be considered in detail.

ease among the abstainers and only 1 of each among the temperate; 2 deaths from appendicitis among abstainers and none among the temperate, and, lastly, 3 suicides among the abstainers and only 2 among the temperate. These factors alone would account for part of the difference, and it is possible that some of those claiming to be abstainers made

TABLE B.—ISSUE OF 1907-1912. EXPOSURE OF 1907-1913. SUMMARY. ALL AGES—POLICY YEARS 1-6 BY THE M. A. TABLE

	ON APPLICATIONS				ON AMOUNTS			
	EXPOSURES	DEATHS		RATIO	EXPOSURES	DEATH-CLAIMS		RATIO
		ACTUAL	EXPECTED			ACTUAL	EXPECTED	
CLASS 224—INDOOR CLERICAL SERVICE								
Total class	39,657	90	192.110	46.9	$70,181,750	$174,700	$345,864	50.5
Total abstainer	16,979	37	76.816	48.1	26,726,975	61,600	122,549	50.3
Temperate	19,926	44	99.790	44.0	38,139,375	90,600	193,151	46.9
Moderate	2,752	9	15.504	58.1	5,315,400	22,500	30,164	74.5
CLASS 226—MERCHANTS AND DEALERS								
Total class	58,090	243	389.150	62.5	$197,852,400	$1,058,900	$1,491,012	71.1

Temperate	34,616	163	236.324	69.1	125,879,200	868,300	949,396	91.2
Moderate	6,909	38	48.426	78.7	30,552,075	98,800	260,012	38.0
CLASS 229—SALESMEN (NOT IN LIQUOR BUSINESS)								
Total Class	32,157	97	159.918	60.6	$59,569,825	$192,400	$307,907	62.5
Total abstainer	11,443	30	52.144	57.6	16,922,400	43,200	78,997	54.9
Temperate	17,987	55	93.256	58.9	36,541,125	123,200	195,005	63.2
Moderate	2,729	12	14.518	82.7	6,106,300	26,000	33,905	76.7
CLASS 233—FARMERS								
Total class	65,399	243	374.109	64.9	$116,901,250	$467,300	$709,017	65.9
Total abstainer	32,026	103	170.966	60.3	53,510,400	211,000	304,379	69.4
Temperate	32,317	133	196.122	67.8	60,798,850	241,800	388,671	62.9
Moderate	1,058	7	7.021	99.4	2,592,000	14,500	15,944	72.1
CLASS 240—FACTORIES AND MILLS—PROPRIETORS, MANAGERS AND SUPERINTENDENTS								
Total class	15,718	76	114.365	66.4	$88,672,725	$358,600	$709,895	50.6
Total abstainer	3,651	17	26.014	65.5	16,020,225	66,600	120,012	55.5
Temperate	10,135	53	74.645	71.0	60,966,525	279,500	504,909	55.3
Moderate	1,934	6	13.706	43.7	11,685,975	12,500	84,911	14.8
TOTAL CLASSES 224, 226, 229, 233 AND 240 COMBINED								
Total class	211,021	749	1229.652	60.9	$533,177,950	$2,251,900	$3,563,725	63.3
Total abstainer	80,664	229	430.340	53.4	154,601,125	474,200	907,621	52.2
Temperate	114,975	448	700.137	64.1	322,325,075	1,606,400	2,231,135	72.0
Moderate	15,382	72	99.175	72.7	56,251,750	171,300	424,969	40.3
Total non-abstainer	130,357	520	799.312	65.0	$378,576,825	$1,777,700	$2,656,104	66.8

Class 224 represents those engaged in indoor clerical service, numbering 15,402, insured by the Mutual Life during the six years from 1907 to 1912, which is 9.3 per cent. of the total number of entrants. The average amount insured was $1,787, and the average amount of death claims paid was $1,941. There were ninety actual deaths as against 192.1 expected deaths, the ratio of actual to expected being 46.9 per cent. by number and 50.5 per cent. by amount. Dividing these into three groups, it is found that 6,523 indoor clerks, or 42.3 per cent. of the total number, who on entering claimed to be abstainers, gave 37 actual deaths and 76.8 expected, a mortality ratio of 48.1 per cent. by number and 50.3 per cent. by amount. The 7,878 temperate, representing 51.1 per cent. of the total clerks gave 44 actual and 99.8 expected, a ratio of 44.0 per cent. by number and 46.9 per cent. by amount. The 1,001 entrants, or 6.5 per cent. who stated that they drank daily but not in excess of the medical limit, showed 9 actual and 15.5 expected deaths, a mortality ratio of 58.1 per cent. by number and 74.5 per cent. by amount. The superiority of the temperate group to the total abstainers in this class is difficult to account for. A study of the cases shows that there were 2 deaths from diabetes among the abstainers and none among the temperate; 3 deaths from apoplexy and 3 from heart disease among the abstainers and only 1 of each among the temperate; 2 deaths from appendicitis among abstainers and none among the temperate, and, lastly, 3 suicides among the abstainers and only 2 among the temperate. These factors alone would account for part of the difference, and it is possible that some of those claiming to be abstainers made false statements as to habits when applying for insurance, or, on the other hand, were abstainers because of impairments concealed from the examiner.

Class 226, merchants and dealers, represents 22,379 insured, or 13.6 per cent. of the total number of entrants with an average amount insured of $3,428, and death claims paid $4,358. The 243 actual as against the 389.2 expected deaths show a ratio of 62.5 per cent. by number and 71.1 per cent. by amount. The 6,500 abstainers, 29.0 per cent. of the total, with 42 actual and 104.4 expected deaths, give a mortality ratio of 40.2 per cent. by number and 32.6 per cent. by amount. The 13,332 entrants in the temperate group, or 59.5 per cent. with 163 actual and 236.3 expected deaths, give a mortality ratio of 69.1 per cent. by number and 91.2 per cent. by amount. Finally, the 2,547 entrants in the moderate group, with 38 actual and 48.4 expected deaths, give a ratio of 78.7 per cent. by number and 38.0 per cent. by amount. The mortality ratio of abstainers in this class is, therefore, superior to the temperate and the latter in turn is superior to the moderate in death-ratio but not in loss-ratio.

Class 229—Traveling Salesmen and Collectors—Not in Liquor Business. Among the 13,132 cases, or 8.0 per cent. of the total number of entrants, there were 97 actual and 159.9 expected deaths.

The mortality ratio was 60.6 per cent. by number and 62.5 per cent. by amount, the average amount insured being $1,865, and the average amount of death claims being $1,984. Of the 4,738 abstainers representing 36.1 per cent of the total number, there were 30 actual and 52.1 expected deaths. The percentage of deaths was 57.6 per cent. and losses 54.9 per cent. The 7,327 entrants in the temperate section, or 55.8 per cent. with 55 actual and 93.3 expected deaths, gave us a mortality ratio of 58.9 per cent. by number and 63.2 per cent. by amount. Finally, the 1,067 moderate drinkers, 8.1 per cent., with 12 actual and 14.5 expected deaths, showed a ratio of 82.7 per cent. by number and 76.7 per cent. by amount. The difference in the death-ratio between the abstainers and temperate was slight, but the former shows a superiority over the latter of 8.3 per cent. in loss-ratio. The abstainers, however, show a superiority over the moderate of 25.1 per cent. by number and 21.8 per cent. by amount.

Class 233, Farmers, constitutes the largest in number of entrants, being 27,859, or 16.9 per cent. of the total, but it is not the largest in amount of insurance. The average amount insured was $1,-815 as compared with $3,428 for the merchants and dealers and $5,748 for the proprietors, managers, and superintendents of factories and mills. The actual deaths were 243, expected 374.1, the mortality ratio being 64.9 per cent. by number and 65.9 per cent. by amount. As a class it furnished the largest number of abstainers, 13,767 or 49.3 per cent. The 103 actual and 171.0 expected deaths gave a mortality ratio of 60.3 per cent. by number and 69.4 per cent. by amount. In the Temperate group there were 13,633 entrants representing 48.8 per cent., with 133 actual and 196.1 expected deaths, giving a mortality ratio of 67.8 per cent. by number and 62.9 per cent. by amount. In the Moderate group there were only 459 entrants, or 1.6 per cent. of the total in this class, giving 7 actual and 7.0 expected deaths, a mortality ratio of 99.4 per cent. by number and 72.1 per cent. by amount. The Abstainers are, therefore, superior to the Temperate group in the death-ratio by 7.5 per cent., but inferior in the loss-ratio by 6.5 per cent. Among the Moderate group the percentage of deaths is 39.19 per cent. above the Abstainers, but the percentage of losses is only about 3 per cent. above.

Class 240, Proprietors, Managers and Superintendents of Factories and Mills—has 5,824 entrants, or 3.5 per cent. of the total. The average amount insured was $5,748 and the average death claim $4,718, and the 76 actual and 114.4 expected deaths give a mortality ratio of 66.4 per cent. by number and 50.6 per cent. by amount. The 1,343 Abstainers, 23.1 per cent. with 17 actual and 26.0 expected deaths show a ratio of 65.5 per cent. by number and 55.5 per cent. by amount. The 3,764 Temperate, 64.7 per cent. with 53 actual and 74.6 expected deaths give a mortality of 71.0 per cent. by number and 55.3 per cent. by amount. On the other hand, the 717 Moderate Drinkers, or 12.3 per cent., give 6 actual as against 13.7 expected deaths, a ratio of 43.7 per cent. by number and only 14.8 per cent. by amount, which is superior to the Abstainers by about 21.8 per cent. by number and 40.7 per cent. by amount. This is the only class in which the Moderate group is superior to both the Abstainers and Temperate and the apparent result is doubtless due to the fact that the numbers are too small to warrant any satisfactory conclusions therefrom.

The combination of the five classes gives a mortality ratio of 53.4 per cent. by number and 52.2 per cent. by amount for Abstainers; 64.1 per cent. by number and 72.0 per cent. by amount for Temperate; and 72.7 per cent. by number and 40.3 per cent. by amount for Moderate. As the mortality ratio for the aggregate experience of the five classes was 69.9 per cent. by number and 63.3 per cent. by amount, the Abstainers show a lower mortality ratio, equivalent to a decrease of 33 deaths or 4 deaths per 10,000 exposures. The Temperate show a higher ratio, which is equivalent to an increase of 22 deaths, or about 2 deaths per 10,000; and the Moderate show a still higher mortality ratio, which is equivalent to an increase of 12 deaths, or 8 per 10,000 exposures. Adding together the Temperate and Moderate groups, there is a mortality ratio for Non-Abstainers of 65.0 per cent. by number and 66.8 per cent. by amount. The non-abstainers are, therefore, inferior to Abstainers by 11.6 per cent. by number and 14.6 per cent. by amount, which is equivalent to an increase of 93 deaths, or 7 per 10,000 exposures.

A careful study of the causes of the deaths showed that, of the decrease of 33 deaths among Abstainers, 28 were from tuberculosis, cancer, apoplexy, heart disease and pneumonia combined, and 5 were from cirrhosis of the liver, Bright's disease, and suicide. Amond the Temperate group, the increase of 22 deaths was chiefly from cancer, apoplexy, heart disease and pneumonia combined, and 5 were from cirrhosis of the liver, Bright's disease and suicide. Of the 12 extra deaths in the Moderate group, 5 were from suicide, 3 from cirrhosis of the liver, 2 from heart disease, and 1 each from pneumonia and Bright's disease.

I will next call your attention to Table "C" showing the ages at which the policies were issued.

As the limited number of deaths does not warrant the study of each class separately, they have been combined and presented so as to show the results for the three respective groups. A study of the table shows that, at every age group, the ratio of the actual to expected deaths is lower with the Abstainers than the Temperate and the mortality of the Temperate is lower than the Moderate. Considering the paucity of the data, regularity of progression at each age-group cannot be expected, but the striking fact remains that there is a difference of nineteen points between the Total Abstainers and the Moderate group, and nine points between the Temperate and the Moderate group.

For the purpose of confirming in a general way the experience of the Mutual Life as to the superiority of the Abstainer class to the Non-Abstainers, I will refer briefly to a few other companies, where a similar class of observations has been reported.

The United Kingdom Temperance and General Provident Institution of England presented its mortality experience of Abstainers and Non-Abstainers, covering a period of 45 years, from 1866 to 1910 inclusive. There were 8,988 actual deaths as against 12,754 expected deaths according to the O. M. table in the Abstainer section; and 14,711 actual as against 15,794 in the Non-Abstainer section. The mortality ratio was, therefore, about 70 per cent. for the former and about 93 per cent. for the latter section, a difference of 23 points in favor of

TABLE C.—ISSUE OF 1907-1912. EXPOSURE OF 1907-1913. SUMMARY BY AGES—POLICY YEARS 1-6. BY THE M.-A. TABLE

Ages	On Applications: Exposures	On Applications: Deaths: Actual	On Applications: Deaths: Expected	On Applications: Ratio	On Amounts: Exposures	On Amounts: Death-claims: Actual	On Amounts: Death-claims: Expected	On Amounts: Ratio

the Abstainers. In the last quinquennium, 1906-1910, which corresponds approximately with the Mutual Life experience, 1907-1912, the mortality ratio was 65 per cent. for Abstainers and 83 per cent. for Non-Abstainers, a difference of 18 points in favor of Abstainers.

The Sceptre Life Assurance Company of England submitted the mortality experience of Abstainers and Non-Abstainers for the 27 years from 1884 to 1910. There were 1,214 actual and 2,311 expected deaths in the Abstainer section; and 2,674 actual and 3,352 expected deaths in the Non-Abstainer section, the mortality ratio being about 53 per cent. for the former and about 80 per cent. for the latter, a difference of 27 points. In the period from 1904 to 1910 there were 422 actual and 871 expected deaths in the Abstainer section; and 794 actual and 982 expected deaths in the Non-Abstainer section, the ratio being about 49 per cent. for the former and about 81 per cent. for the latter, a difference of 32 points.

The Scottish Temperance Life Assurance Company of Scotland published the mortality experience of Abstainers and Non-Abstainers for the 25 years from 1883 to 1907. It showed a ratio of 46 per cent. for Abstainers and 64 per cent. for Non-Abstainers, a difference of 18 points. There were 718 actual and 1,545 expected deaths for the former and 348 actual and 542 expected deaths for the latter. In the last quinquennium, 1903-1907, there were 298 actual and 609 expected deaths in the Abstainer and 123 actual and 223 expected deaths in the Non-Abstainer section, the mortality ratio being 49 per cent. for the former and 55 per cent. for the latter section, a difference of 6 points.

The Australian Temperance and General Life Assurance Society of Australia, in the 10 year period from 1900 to 1910, showed a loss-ratio of about 47 per cent. for Abstainers and about 76 per cent. for Non-Abstainers, a difference of 29 points in favor of Abstainers.

The Manufacturers' Life Insurance Company of Canada, as recorded in Dr. T. F. McMahon's admirable paper, read before this Association, showed a mortality ratio of about 37 per cent. for Abstainers and about 66 per cent. for Non-Abstainers, a difference of 29 points in 9 years' experience from 1902 to 1910.

Dr. E. W. Dwight, in his discussion of Dr. McMahon's paper in 1911, reported the experience of the New England Mutual Life Insurance Company as follows: Abstainers show roughly, a mortality of 59 per cent. of the American Table; Rarely Use, 71 per cent.; Temperate, 84 per cent., and Moderate, 125 per cent. He further presented an interesting comparison showing the results with reference to tobacco. "The Total Abstainers from tobacco had a mortality of 57 per cent. as against 59 per cent. for the Total Abstainer from alcohol; the Rarely Use, 72 per cent. as against 71 per cent. from alcohol; the Temperate, 84 per cent. as against 84 per cent. from alcohol, and the Moderate, 93 per cent. as against 125 per cent. from alcohol." Referring to numbers, Dr. Dwight further stated: "Out of 180,000 cards, 42,700 were total abstainers from alcohol—at least they said they were—while the total abstainers from tobacco were 41,000—almost exactly the same number; 13,000 rarely used tobacco, while 20,000 rarely used alcohol.

In October, 1913, Dr. R. L. Lounsberry reported before this Association the experience of the Security Mutual Life Insurance Company with Total Abstainers, but unfortunately, did not have the results with Non-Abstainers of the same period for comparison. The total number of exposures was 24,725; Actual Losses, 80; Expected Losses by American Table, 240.58; Ratio, 33.25 per cent. By

amounts the figures were: Total Exposed to Risk, $39,337,044; Actual Losses, $188,160; Expected Losses, $396,388; Ratio, 47.47 per cent.

A—Abstainers; B—Beer or wine drinkers; D—Whiskey drinkers and a few large users of beer or wine.

In the June, 1915, number of the *American Underwriter* the editor, Mr. Edward Bunnell Phelps, presented a tabulation furnished by the Actuarial Department of the Northwestern Mutual Life Insurance Company showing the mortality experience of that company on abstainers and non-abstainers for the years 1886 to 1895 inclusive, figured to the end of 1900. As the tables are of interest, in that they furnish results among beer and wine drinkers and whiskey drinkers, in separate classes, I have taken the liberty of copying them and presenting them for inspection. (See above.)

The ratio of actual to expected mortality for all ages among the drinkers of beer and light wines was but 54.35 per cent. as against 66.84 per cent. for whiskey drinkers, a difference of 12.49 per cent., or about ten points less than that found between abstainers and non-abstainers, as an average experience of all observations quoted, with the exception of this group. It might be noted, however, that in age-groups 30 to 39 and 50 to 59, the ratios were lower in the case of users of beer and light wines than in the case of Total Abstainers, and the total ratio of actual to expected mortality was but 11.15 per cent. higher in the case of Non-Abstainers as compared with Total Abstainers. As it is stated in the article quoted that the Northwestern Mutual retained the right to cancel policies for intemperance during the lifetime of the insured, it is possible that the striking differences in their results may in a measure be accounted for by that fact. No mention is made as to the mortality table followed in compiling their figures and it has been deemed best to exclude them in estimating the approximate totals of all observations.

Returning to the consideration of the experience of the Mutual Life Insurance Company, I will refer to the facts brought out by Mr. McClintock in 1895, showing the results with Abstainers and Non-Abstainers for the 15 years from 1875 to 1889. The available material started with the year 1875 when the company's application blank first contained the direct question as to the use of alcohol, requiring a definite answer, "Yes" or "No." The experience was based on amount of insurance rather than policies, and the American Table was adopted as the standard for comparison. To eliminate the element of medical selection, 40 per cent. of the loss expected by the Standard Table was taken for the first policy year; 70 per cent. for the second, third and fourth policy years, and 87.5 per cent. for each policy year after the fifth. The maximum expected loss among Abstainers was $5,455,669, whereas the actual loss was $4,251,050, a ratio of 77.8 per cent. With the Non-Abstainers the expected was $9,829,462, and the actual $9,469,407, a ratio of 96.6 per cent., a difference of 18.8 points in favor of Abstainers.

For further study and comparison, I present Table "D" giving ages at issue and results.

In the earlier period, 1875 to 1888, the Abstainers gave a loss-ratio of 71 per cent. for ages 15-39, and 85 per cent. for ages 40 and over, a difference of 14 per cent. in favor of the younger age group; and the Non-Abstainers gave a loss-ratio of 83 per cent. for ages 15-39 and 107 per cent. for ages

Total	130,357	520	799 312	65 0	$378,576,825	$1,777,700	$2,656,104	66 8

40 and over, a difference of 24 per cent. in favor of the younger group.

In the later period, 1907 to 1912, the Abstainers exhibit a loss-ratio of 53.8 per cent. for ages 15-39, and 50.6 per cent. for ages 40 and over; and the Non-Abstainers give a loss-ratio of 70.2 per cent. for ages 15-39, and 65.2 per cent. for ages 40 and over. These ratios are very consistent in the second period for the reason that the proportion of Abstainers that begin drinking above middle age is supposed to be smaller than below middle age. A higher loss-ratio is found, therefore, in the younger group than in the older among Abstainers. The higher ratio among the Non-Abstainers in the younger age group is probably due to the same cause, namely, that the proportion of intemperate that become hard drinkers is larger at the younger than at the older ages. In the earlier period just the contrary is true; the younger age group shows a diminution of 14 points among Abstainers and 24 points among Non-Abstainers as compared with the older age group. This anomaly in the earlier period may be due to two causes: First, the use of the American Table as a standard of comparison instead of the M. A. Table accounts largely for the difference in the loss-ratio observed between those entering at young and old ages, as the rate of mortality by the American Table is 170 per cent. that of the M. A. Table up to age 40, and then the ratio decreases rapidly to age 70, when it is 100.5 per cent.; second, the statistics in the earlier period were not homogeneous. They were based upon the total Domestic Business, whereas in the later period, only 5 occupation classes were taken and the Southern States were eliminated. This lack of homogeneity is also responsible for the greater difference of the mortality ratios between Abstainers and Non-Abstainers of the first period, as compared with the second period, there being a difference of 18.8 points in favor of Abstainers in the former and but 14.6 points in the latter, calculated by amounts, and only 11.6 points by applications.

Owing to the technical differences in the experiences quoted and standards followed in calculation, it is impossible to summarize accurately the total results of all of the figures submitted from the various companies, but a general observation excluding the Northwestern, allowing for these differences, furnishes an interesting conclusion. It shows that, roughly, the average mortality ratio among Total Abstainers from alcohol is 68.4 per cent., whereas that of the Non-Abstainers is 91.5 per cent., a difference of 23.1 per cent. This means a reduction of about 2 1 3 years in the average life of the Non-Abstainer, below that of the Abstainer. Although somewhat less than the period indicated as a result of previous calculations, it is most significant and far-reaching in its importance.

At a time when the attention of the entire world is directed to the question of the effects of alcohol, it is well to have as reliable data as possible from which to form conclusions. I submit, therefore, to this Association, as the representative body dealing with medical statistics, this contribution, trusting that Table "B" may serve, until a larger volume of material is presented, as an accurate scientific standard of the comparative mortality among Abstainers and Non-Abstainers from alcohol.

149 West Seventy-third Street.

DEMENTIA AND MULTIPLE TUBERCULOUS BRAIN ABSCESSES.

By G. B. HASSIN, M.D.,

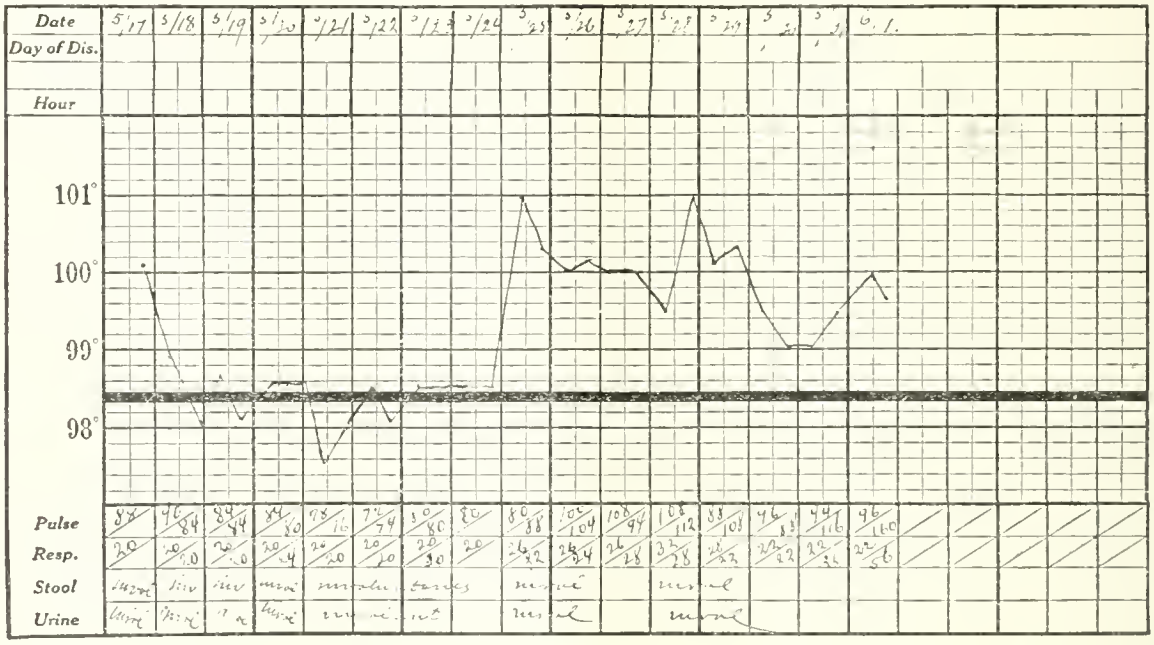
CHICAGO

ATTENDING NEUROLOGIST, COOK COUNTY HOSPITAL.

Multiple brain abscesses are, as a rule, of metastatic origin, being caused by some suppuration in organs more or less remotely situated from the brain tissues proper. Of these organs the lungs, when affected, are the most frequent cause of these abscesses, and any lung lesion, as empyema, pneumonia, putrid bronchitis, abscess, or tuberculosis may be their primary cause. According to Roger[1] there were altogether about eight cases reported in which tuberculosis of the lungs was the original cause of brain abscesses, and such an etiology is justly considered very rare and even exceptional. Much rarer still is a simultaneous occurrence of multiple cerebral abscesses and dementia, and it is

occasionally very hard to interpret such cases properly. I mean to say that cases do occur in which multiple brain abscesses are associated with some mental disorder, in which both mental and nervous symptoms are equally pronounced, and in which an explanation of these symptoms, of their mutual relationship, of their diagnosis, is quite difficult. Such was the case in our patient:

Mr. K., 60 years old, a widower. He entered the Cook County Hospital on May 17, 1915, complaining of headache, cough, general weakness, and pain in the chest. These troubles, he said, had existed for about ten days, and began with a slight chill. He did not go to bed, however, until two days before he entered the hospital. The pain in the chest was especially severe during deep breathing. The cough was moist, but without blood. Any previous diseases he denied, but his daughter stated that he was an inmate of an insane asylum some time before. It could not be ascertained how long he had been in the asylum, or what was the nature of the psychosis he had been suffering from. The patient has been drinking eight or ten glasses of beer daily, and about two glasses of whiskey. The examination revealed a rather poorly nourished white man, weighing about 145 pounds. He was brought to the



ward on a stretcher, was very apathetic, refused to answer questions, or answered them only after repeated urging, and often contradicted himself. Obviously, any history obtained from him must be unreliable. He had involuntary discharges on admission, and a temperature of 100.2°, respiration 20, pulse 88 (see chart). The physical examination did not reveal any cranial anomalies, or head injuries, or any disease of the nose, ears, etc. The teeth of the upper jaw were missing, and the lower jaw showed badly decayed stumps and a marked pyorrhea. The tongue was coated and tremulous, the chest symmetrical and well developed. There were no râles in the lungs, no areas of dullness, though the breath sounds were high pitched and harsh over the left chest just below the clavicle. The abdomen and genitalia showed nothing abnormal. The sensibility, the reflexes, including the pupils, the fundi were normal, while the bladder and rectum reflexes were lost, *i.e.* there was incontinence of both. There was some rigidity in the legs with a questionable Babinski on both sides. A proper neurological examination could not be made as the patient did not cooperate, in fact he resisted any examination, and refused to answer most of the questions. He was, as we said, very dull, apathetic, and completely disoriented as to time, place, persons, and recent events. The slightest mental effort would tire him out, and then he would not even attempt to answer the simplest questions. The sputum showed the presence of pneumococci, but no tubercle bacilli. The urine, blood, and spinal fluid were normal. The blood pressure was 125 systolic, 90 diastolic.

During the patient's stay in the hospital he developed, six days after his admission, additional mental symptoms. Thus he aimlessly walked about the ward hiding the drinking cups under beds. But soon, about two days later, he improved and wanted to go home. Suddenly, however, on May 25, he showed a rise in temperature, accompanied by clonic convulsions which first were general, but shortly became localized in the face, left shoulder, and left hand. A new spinal puncture gave a clear, serous fluid, under slightly increased pressure, with no microorganisms in it, but a positive globulin reaction. At noon of the same day the head and the eyes, which were very much congested, were turned to the right. The pupillary reaction was present, but very sluggish, neck rigidity was absent. The convulsions were rapidly following each other in the form of rapid twitchings in the face, left arm, and hand. The blood count gave 7,200 leucocytes. The patient was very irrational and resistive. The following day the same symptoms, conjugated deviation of the eyes and head toward the right, marked congestion of the eyes, the same continuous convulsions and involuntary discharges. The fundi showed no changes, and there was some response to painful stimuli, but none to questions. On May 28, *i.e.* eleven days after admission to the hospital, the convulsions ceased. The patient became semi-stuporous, rigid, and developed some râles in the lungs. Three days later, June 1, he died, a week after the onset of the brain symptoms, two weeks after entrance to the hospital, and three weeks after the beginning of the disease.

From this brief record it can be seen that no neuropathological symptoms or signs could be discovered at the time the patient was admitted to the hospital, but mental symptoms were quite evident, and a tentative diagnosis of senile dementia was made. The important brain symptoms, as convulsions, conjugated deviation of the eyes and head showed a week later, the convulsions having had the form of so-called epilepsia continua, *i.e.* there were continuous clonic contractions in the left leg, left arm, and face which persisted day and night until the patient became stuporous. We assumed that the epilepsia continua was caused by some meningeal or cortical irritation, and a diagnosis of internal hemorrhagic pachymeningitis was made. Such a diagnosis is, according to Oppenheim,[2] more or less justified when the above-mentioned symptoms occur in the presence of alcoholism, senile

dementia, skull lesions, etc. The necropsy, however, showed nothing of the kind:

The meninges were normal in appearance, and showed no adhesions, but the pia-arachnoid membranes were raised from the cortex by a generous layer of clear cerebrospinal fluid. The surface of the hemispheres was not flattened, but the right hemisphere was bulging and fluctuating, especially around the middle portion of the brain, along the fissure of Rolando. The brain tissue was here very soft and moist. Frontal sections of the brain revealed the presence of multiple sharply defined abscesses varying in size from that of an English walnut to a hazelnut. The largest one was situated on the right side just *beneath* the motor area of the cortex, and corresponded to the point of fluctuation mentioned above. Another of smaller size was found in the left hemisphere. The abscesses did not involve the large ganglia, did not communicate with the ventricles, had no capsules and were separated from the cortex by an area of seemingly normal white substance. The abscess cavities were filled with a pea-green to yellow colored pus of a very offensive odor. Smaller abscesses to the number of six were found in the parietal and occipital lobes, and patches of encephalitis and softening were found in the paracentral lobe. The cerebellum, pons, and medulla were normal. In addition multiple abscesses were found in the kidneys, the pus having shown the same properties as in the brain abscesses. Cultures and smears made from the pus proved sterile. There was also a chronic ulcerative and miliary tuberculosis of the lungs, combined with a tuberculous osteomyelitis of the sternum and senile sclerosis of the aorta.

The necropsy thus proved that the patient's cerebral symptoms were due not to a pachymeningitis, but to a multiple brain abscess coupled with an encephalitis. These findings were rather a surprise, as nothing whatever indicated a possibility of an abscess in the brain, except possibly the presence of the continuous clonic convulsions in the left side of the body which we interpreted as epilepsia continua. Nähter[3] and Seeligmüller consider Jacksonian epileptic convulsions typical for pulmonic brain abscesses, but Martius[4] found them absent in 50 per cent. of cases, and then again the epilepsia continua variety also may be caused by any cortical irritation, as encephalitis, gumma, or pachymeningitis hemorrhagica interna.[5] The condition of the lungs was suspicious, but the absence of tubercle bacilli and of pronounced destructive lung lesions did not permit of the suspicion of tuberculosis of the lungs as the possible cause of the brain symptoms. The same can be said of the kidneys which showed no clinical evidence of suppuration, as the urine was all the time negative. Therefore, we were rather inclined to the diagnosis of internal hemorrhagic pachymeningitis for which spoke the history of alcoholism, of previous mental disorder, the motor restlessness, the epilepsia continua, the conjugated deviation of the head and eyes, the resistance, and the absence of basal nerve involvement. My case bears out the correctness of Oppenheim and Cassirer's[6] statement that the diagnosis of a brain abscess, especially a metastatic one, is in the majority of cases impossible, and is first revealed at the necropsy. The abscesses were multiple in both hemispheres, also in the kidneys, which fact speaks for their metastatic nature. The only organ in which they could originate, in our patient, was the lungs, which according to R. Meyer[7] are, next to trauma and otitis, the most common source of brain abscesses. The absence of incapsulation and of optic neuritis indicates that the abscesses were young, not older than four or eight weeks, during which period a membrane usually forms. The absence of tubercle bacilli or of any microorganisms does not speak against their tuberculous or some other microbic origin, as in similar cases, like those reported by Helbron,[8] Roger,[1] and Southard and Ayer,[9] no tubercle bacilli were found. On the other hand, in Fraenkel's[10] case the pulmonic brain abscess was loaded with tubercle bacilli, as if the abscess presented a pure culture of these microorganisms.

The metastatic abscesses of the brain must thus be considered the direct cause of the nervous symptoms and of our patient's death. It remains to be determined whether this etiology had any bearing on his mental condition. It is an established fact that in every case of a brain abscess some psychical anomalies are present. Thus, Huguenin[11] in his classical monograph states that in brain abscess patients "an accurate investigation of psychical functions discovers a psychical defect, a weakness of memory as well as of rapidity and readiness of thinking and judging under such circumstances." If we remember that an abscess may be hidden in the brain for a considerable length of time, as twenty years in the case of Nauwerk,[12] or twenty-six years in that of Haerlin,[13] without causing any definite or marked nervous symptoms, it will be understood that the only clinical symptoms in such cases will be psychic, in the form of various psychoses, as dementia, melancholic states, hypochondriasis, and so forth. Quite a number of cases have been reported in which various psychoses were associated with brain abscesses and ascribed to the latter. Here belong the cases of Zeller,[14] Schmidt,[15] Kern,[16] Dupré and Devaux,[17] Porot,[18] Amberg,[19] Southard and Ayer,[9] Henderson, Muirhead, and Frazer,[20] and Huguenin.[11] In Zeller's case the clinical picture was that of paralytic dementia, while the necropsy showed multiple metastatic abscesses of the right frontal lobe and of both optic thalmi. Schmidt's patient, twenty-four years old, gave the symptoms of catatonia, combined with a cerebral abscess of the superior parietal lobe caused by erysipelas. He could not prove any connection between the brain abscess and the psychosis. More positive is Kern, whose patient also had catatonia associated with tuberculosis of the ear. The necropsy revealed a brain abscess, and Kern thinks that in such a case toxins from the abscess may affect the general nutrition of the brain and give a clinical picture of catatonia. Of the same opinion are Dupré and Devaux. They found in a fifty-five-year-old tuberculous patient multiple brain abscesses that gave, as in my patient, clinical symptoms of meningitis, combined with a psychosis, shown by apathy, torpor, aphasia, and so-called psychical blindness. The post mortem showed absence of meningitis, but one frontal abscess and one larger one in the middle portion of the left hemisphere, combined with necrosis of the cortex. These cortical changes and the psychic disturbances they ascribe to the intoxication exclusively. In Porot's patient, an epileptic, an old encysted abscess was found, and Amberg speaks of a patient who was considered a hypochrondiac, as he always was complaining of having a brain abscess which was, in fact, found after the patient died. Southard and Ayer's patient, twenty-five years old, had tuberculosis of the lungs, associated with dementia paranoides, and was an inmate of an insane asylum for five years. The necropsy showed multiple abscesses of the brain and cerebellum, and also pulmonary tuberculosis. They think that the lung lesion had some influence upon the patient's mental state by caus-

ing toxemia. The same explanation is given by Henderson, Muirhead, and Frazer for the psychic disorders in their patient with an extradural brain abscess and labyrinthine troubles. Finally I must mention the case of Huguenin, whose patient presented the same symptoms as mine and where a diagnosis of intermittent fever was made. The autopsy revealed an abscess of the left frontal lobe and right temporal lobe, and cheesy bronchial glands. The sole comment Huguenin makes is that the case was mistaken for intermittent fever of an irregular type, an error, as he puts it, "hardly to be avoided. In my opinion, the psychosis of Huguenin's patient was, as in the cases of the authors quoted, due to toxemia from the multiple brain abscesses. The toxemia, as I pointed out, was considered by the majority of authors the direct cause of the abnormal mental states of their patients, and it is proper to ask if this etiology is not of the same value in my patient. Of course, the to me unknown psychosis he had been suffering from long before he entered the hospital, had no connection whatsoever with his brain abscesses, as the latter, undoubtedly, were of recent date. But the latest abnormal state, which I myself witnessed during the last two weeks of the patient's life, and which much resembled senile dementia, was most probably the direct result of the multiple brain abscesses, just as in the cases of the authors previously mentioned.

INFECTIOUS DISEASES OF THE INTRAMURAL INSANE: THEIR PREVENTION AND TREATMENT.

By J. ALLEN JACKSON, M.D.,

PHILADELPHIA, PA.

CHIEF RESIDENT PHYSICIAN, PHILADELPHIA HOSPITAL FOR THE INSANE.

THE greatest phobia confronting the average hospital superintendent is the fear of fire, accidents, and infectious diseases. These three conditions are fraught with grave and serious dangers. In a series of articles trying to cover these most important subjects, ranking in their rotation of gravity, infectious diseases seem paramount, as, at the present time, the modern hospital is well equipped, fire-proof, and all precautions are taken against fire. Accidents are prone to happen in any institution and the prevention of these depends a great deal on the age, type, structural conditions, limited amount of help and so on, of the hospital in question. All institutions, however, are prone to outbreaks of infectious diseases.

In the Philadelphia Hospital for the Insane, that much berated institution, with its lack of proper buildings, overcrowded conditions, insufficient employees, and with the highest admission rate of any hospital in Pennsylvania, its system of prevention and treatment of infectious diseases is possibly not excelled, as, in the confines of these monasterial walls there are many niches, so to speak, which are of extreme aid in the prevention and the treatment of infectious diseases. The records of this hospital for years past will show a low percentage of infectious diseases, which is rather astounding. This does not apply to tuberculosis, but upon the other hand, the death rate from tuberculosis does not excel that of other institutions.

The exanthemata.—Of acute exanthemata, measles is probably the most common yet the least harmful of all diseases, on account of the fact that the majority of patients who contract the disease are adults and receive proper medication while ill. About four years ago we had a few cases of measles develop in the male and female divisions but, because of thorough isolation, quick diagnosis, and appropriate treatment, no untoward effects were noticed, and a very few cases developed.

As to scarlet fever, so far as we are able to determine from the records we have not had any cases of this disease; the same applies to smallpox with the exception that within the past two or three years we were twice quarantined owing to the development of two cases of smallpox at different intervals in the Philadelphia General Hospital.

The prevention of these diseases deals not so much with causes from within but with those coming from without; for instance, lax quarantine of a Bureau of Health would permit the members of infected districts to visit these institutions. In Philadelphia, however, the excellent system of the Bureau of Health prevents any such avenues of infection, as all known cases of quarantinable diseases are strictly held as such. Occasionally a patient from an infected household is admitted to the in-

stitution and forms a nucleus of trouble, if not properly diagnosed and quarantined. In preventing this, however, many institutions require physicians to certify that patients who are to be admitted have not been exposed to any infectious diseases; if the necessity arise, whereby such a case should be admitted, of course the only course to pursue is to isolate and handle the case as best possible; an excellent ruling of this hospital for years past has been that all patients should be vaccinated, and if there is at any time a smallpox scare within the city, we usually insist that all patients be revaccinated who do not have a perfect scar formation.

Parasitic diseases are quite common in institutions, especially scabies and pediculosis. Diagnosis of these conditions is usually very simple; prevention and active treatment, however, are very important or it will be necessary to quarantine several sections until the pests are eliminated; to avoid any of these conditions the ward should be kept sanitary, the laundry properly disinfected, as well as towels, body clothes, bed linen, and so on. The patient's body should be inspected on bathing days, his head when the morning toilet is made, and the clothing when it goes to and comes from the laundry. The treatment of these conditions briefly consists of isolation, sanitation, and disinfection.

Scabies is the most prone to occur, particularly in dealing with indigent cases and the patients are visited by members of the family who come from the slums of the city. It is not uncommon to find a patient developing scabies after having been visited by a scabetic relative, or having pediculi after having been visited by a pediculosis victim. Sulphur for scabies, fishberry for lice, frequent spraying of beds with a combination of carbolic and kerosene, and replacement of all defective wood work with cement, will eliminate vermin. Fleas sometimes, if cats are around, will thrive in unsanitary cellars.

In indigent hospitals where the maintenance fund is limited, combs and brushes used for making the toilet should be disinfected before being carried from one head to another. Some patients are distinct breeders and, when diagnosed as such, their hair should be either clipped or attractively bobbed, until the source of infection is eliminated. Intestinal parasites in this institution are very uncommon, save for an ameba described by Rosenberger and Terrill, which is apparently of a harmless type and affords no occasion for worriment. This may bear a relation to the ameba found in pyorrhea alveolaris. Although Barrett's first work included a study of a group of cases in this department, and the presence of amebæ affords a plausible cause for pyorrhea, the subject is still open for further study. At the present time, we are conducting some investigations in conjunction with Barrett along this line of work. In this connection, however, it is absolutely essential to keep the mouths and teeth of insane patients in the very best hygienic condition; many State hospitals provide dentists for this line of work; the majority of their work consists, however, in extractions, fillings, and the making of plates. A systematic survey of every patient in hospitals for the insane, by a paid dentist or dental interne, would, no doubt, improve the general health of many patients. This work should include also not only the convalescent, quiet, and mild cases, but the refractory and demented group as well. During the past few years we have had such a systematic extraction and cleansing of patients' teeth in this department. Sometimes food will stain the patients' teeth, particularly molasses of a low grade; therefore, the question of food should always be borne in mind. Meats and vegetables should be inspected at the time of delivery as well as at the time of preparation to eliminate any possible infections of parasitic origin.

Pellagra.—Even if the etiology and pathology of pellagra are still debatable questions from an institutional standpoint, these cases should be handled on a strictly sanitary and hygienic basis. Those who are familiar with this disease, particularly in the hospitals for the insane in the Southern States, appreciate the loathsomeness of the condition, the marked emaciation, increased salivation, diarrhea, and general uncleanliness of the patient, and would certainly insist on isolation, segregation, disinfection, sunshine, and fresh air. Having such a picture in view of the condition, tuberculous shacks and pavilions afford an excellent method for caring for this particular group of cases.

Blockley is the site of many contentions, having its advocates "pros and cons"; pellagra was also found on the "bone" and for years there have been those who argued that we had pellagra and those who said we did not. Within the past five years the writer has seen possibly not more than three cases of true pellagra; in many of the cases in which the diagnosis was made, the diagnosis was based on the marked dermatitis, which was not pellagrous, but solar in origin. The cases lacked the usual characteristic symptoms so common of the disease. Many of these cases of dermatitis cleared up when the patients were given fly tents to protect them from the blazing rays of the summer sun; at the present time we feel we have no pellagra. For those who are inclined to doubt this assertion, the officers of the institution keep an open house and are open for conviction. I am of the opinion that a nutritious diet with a daily change of menu, thus eliminating a constant diet of any one particular food, such as corn bread and molasses, would be a great preventative of pellagra, a disease, no doubt, dependent upon a disturbance of metabolism.

The comparatively recent development of pellagra in this country, its rapid spread, and its invasion into families heretofore unknown to have suffered from the disease, whose dietary to-day is the same as it was years ago, certainly would lead us to infer that the etiology of this disease is of an infectious nature. The fact that the cornmeal and flour which years ago were usually of the home raised variety and ground on the old-fashioned mill-stones, have been replaced by factory-ground products, imported into various country districts, may have something to do with this disease.

Skin diseases.—Diseases of the scalp and other skin diseases, such as psoriasis, tubercular syphilides, and in fact all skin conditions in this particular group, are rather rare among the insane. If one should have such a case in his institution the best course to pursue is to isolate it so far as its bed-linen, hair brushes, clothing, etc., are concerned —being careful not to seclude the patient or deprive him of his pleasures.

Specific infectious diseases.—Erysipelas is undoubtedly the most frequent contagious and highly infectious disease with which the average superintendent of a hospital for the insane, has to contend. The prevention of erysipelas is very essential; great care and precaution should be taken as to sanitary conditions, perfect sterilization of the laundry,

proper disinfection of rubber sheets, frequent renovating of mattresses after disinfection, and so on.

Bed sores, which, by the way, are not very frequent in this institution, by virtue of their conditions, are fertile fields for the streptococci of erysipelas. The prevention of bed sores as well as the proper handling of surgical cases in the infirmaries not only prevent a sporadic case from developing, but undoubtedly check the spread of the disease. One must bear in mind also, the possibility of erysipelas carriers; if such a patient is found it is well to keep him under observation and in strict isolation until all evidences of the disease have disappeared.

Diphtheria, like the exanthemata, in the majority of cases has its origin from without; in other words, cases of diphtheria occurring in this institution are usually brought in by some infected employee or visitor. So important is the relation of the employees to the patient that they should always bear in mind his susceptibility to infectious diseases and the consequent possibilities of infecting the unfortunate under their care. Many hospitals have been put to considerable expense owing to infectious diseases having been brought in by members of the working corps. The writer recalls only one case during the past winter of diphtheria in a patient who undoubtedly contracted it from an employee. The patient was an intelligent individual; she was immediately isolated, and the proper preliminary treatment was given, and later she was transferred to the Hospital for Contagious Diseases. Such a procedure is the usual one for diphtheria, and in case there is no contagious hospital, the case can be properly segregated and treated in the institution without any great fear of impending danger. The practicability of giving antitoxin to the exposed patients would depend a great deal upon whether a subsequent case developed. Personally, I am in favor of waiting to see if a subsequent case does develop, then antitoxin should be given. Never having had a second case develop, I feel quite confident that antitoxin should be freely used among the patients exposed if the occasion should warrant it. Diphtheria is no doubt a contact disease, as I have seen cases suffering from diphtheria taken from crowded wards, isolated, and properly treated and no further cases developed in that ward. I have seen it, not only in this institution, but in other hospitals for the insane.

Vincent's Angina is not an uncommon disease of the insane, particularly so if there has been careless nursing in cleaning the teeth, gums, and lips of toxic cases, as well as advanced paretics and terminal dements. The symptoms are usually those of a persistent ulceration, and smears will reveal the characteristic fusiform bacilli as well as spirilla. Treatment is isolation, being careful to separate the eating utensils, disinfection, and so on, with local applications of weak solution of formalin or copper sulphate.

Influenza, sore throat, and parotitis.—A well established custom in this institution is, if a patient has a sore throat or symptoms of influenza, he is immediately sent to a side room, isolated, and appropriate treatment given. The patients usually make a speedy recovery. They are usually segregated from the rest of the population and in this way these affections are kept under control; too great stress cannot be placed on the early isolation of every case and immediate smear and cultures taken. All eye cases should be handled in a like manner.

Mumps is a very uncommon disease among the insane; this is usually a disease of childhood and the majority of patients come to insane asylums after that age.

Diarrhea.—In many hospital reports we often see statements relative to epidemics of diarrhea; we have had no such epidemics in this institution, with the exception that sometimes after beans have been served, a few patients may develop a diarrhea lasting not more than a day. These are promptly reported, treatment instituted, and the entire situation clears up within 48 hours. The diarrhea common to insane asylums, we have not met. During the summer months if we have a case of diarrhea other than a terminal diarrhea occurring in senile dementia or any terminal state, the patient is isolated and treated as though it were an infectious disease; this, no doubt, has been a great prevention in the occurrence of this disease.

Tetanus, although a very infrequent disease, sometimes develops in insane patients, particularly those who are employed. I recall one such case in the past seven years as having occurred in a patient employed at the farm branch. The point of entrance was a trivial injury to the nail, one which would be readily overlooked on bathing days; the patient shortly thereafter developed tetanus and died. Tetanic serum did very little good as well as enteroclysis of magnesium sulphate, spinal punctures, etc. To overcome such happenings we have instituted a regular examination of all patients employed, in order that no trivial injury or bruise may go unnoticed, thus assuring proper care and attention. In wounds received from rusty nails or under any circumstances which would lead us to suspect the possibility of tetanus developing, serum is given at once.

Tuberculosis.—The high death rate of the insane, due to tuberculosis, can be found in all hospitals ancient and modern. The relation of tuberculosis to insanity has been propounded for several decades. There is one interesting feature, however, on the clinical side of the insane tuberculous which is worthy of mention, viz.: that loss of weight is the principal physical sign significant of the disease; that is, early incipient tuberculosis. Patients rarely cough, seldom expectorate, and few have any intestinal symptoms in the early stages of the disease. Several years ago this institution was covered by experts in the work of tuberculosis and it was amazing that so few cases were found. Some were suspicious, but only a few were classed as positive cases. The ward physicians, upon the other hand, who come in contact daily with these patients, basing their diagnosis upon the attitude of the patient, his languidness, and his emaciation, were not far wrong in their opinions as to the possibility of patients being tuberculous; in fact, upon their reports we based our prospective cases and time has proved that their diagnosis was right. Many patients refuse to breathe, many refuse to cough, many are obstinate; few nasal and oral examinations could be properly made, and the temperature as a rule did not play an important part.

In a special work several years ago at the Central Indiana Hospital for the Insane, the writer endeavored to establish a procedure, following the teaching of Dr. Rosenberger, that acid and alcohol fast bacilli in the feces were significant of tuberculosis, and isolation of the patient would be justified on such findings; there were many difficulties, however, which prevented a diagnosis on these find-

ings, and, at the present time, the writer is convinced that from an institutional standpoint we must rely upon the clinical findings.

Necessarily, the treatment consists of isolation, fresh air, full feeding, proper sanitation, disinfection, and so on; there is no institution so small but what can segregate its known cases of tuberculosis. A ward, or a wing of a ward, may be set aside for their custodial care. Their dishes, utensils and so on can be very readily kept separate, as well as their laundry, bed linen, etc. In the summer time, tents may be erected for the treatment of the bed-ridden cases and a very small infirmary will accommodate those actually confined to bed. In this department we have erected at Byberry City Farms two rather convenient buildings for the treatment of ambulatory cases of tuberculosis; male ambulatory cases are stationed there now; female cases we expect to transfer at an early date. In the interim, we have segregated suspects and treat them along sanitary and hygienic lines. For smaller institutions a small dormitory and tents are extremely useful. The cooking utensils, sputum cups, laundry, etc., are easily disinfected. Garbage should be collected separately and if used for hog feed or chicken feed should be boiled until its contents are perfectly sterilized. The laundry should be collected and carried to the disinfecting plant as soon as soiled; there should be a double system of fly screening so as to eliminate flies. As soon as a patient dies the bed linen, mattress, pillows, rubber sheets and beds should be disinfected as well as single rooms, if such are used, before a new case is confined therein. So far as tuberculosis is concerned every possible measure is used to prevent and cure the disease.

Syphilis.—Occasionally in the admission of cases to hospitals of this class, one sees the secondary eruption of syphilis. Of course, prevention rests upon early diagnosis and strict isolation, as well as the institution of specific treatment.

Paresis.—Owing to our recent enlightened view that the *Treponema pallidum* is found in cases suffering from paresis, the possibility of this disease being infectious is open for discussion. I recall one case of an employee who had been assigned to the paretic room, contracting the disease and dying within a short period; this could not be attributed to the contagiousness of the disease, however, as the man was addicted to the use of alcohol and the possibility of venereal diseases could not be questioned. If the treponemata are found, however, as reported, why is the disease not an infectious one? Until such animal inoculation can be made with cerebrospinal fluid, supposedly infected with *Treponema pallidum*, we are no doubt safe in saying that paresis itself is not a contagious disease. We must bear in mind, at the same time, however, the unexplainable etiology of connubial paresis. Owing to the nature of the disease, aside from its possibility of contagiousness, all of our cases of bed-ridden paresis are assigned to a room known as the "paretic room"; this has many advantages, owing to the uncleanliness of the patients, their tendency to fall out of bed, and predisposition to decubitus. All these can in part be overcome by having them segregated and under specially trained nurses.

Typhoid Fever, in certain districts, is undoubtedly the most serious of all infectious diseases; the prevention of this disease is a very important one and in hospitals located in municipalities, prevention is well covered by the Bureau of Health. In institutions in the agricultural districts, however, due consideration should be given to the very important subjects of a pure-water supply, milk supply and vegetable supply; that is, being careful not to use vegetables raised on farms in infected districts, or in where house soil has been used as fertilizer. The possibility of typhoid carriers, although at times one cannot help but feel that this avenue of infection is exceedingly overrated, must be borne in mind. To ascertain if the employees of an institution are free from typhoid germs seems impracticable at the present time; in view of this the immunization of all asylums' inmates and employees with typhoid vaccine would be advantageous, and such a course, if it could be done, would be the proper course to pursue. Legal compulsory typhoid vaccination would, no doubt, eliminate one of the greatest phobias of hospital superintendents in the city and agricultural districts. If such a case should occur at any given institution much can be done to prevent the spreading of the disease by the proper isolation of the patient; disinfection of excreta, laundry and so on, provided that the source of infection has been extraneous; that is, one outside of the institution, and the water, milk and vegetable supply free from infection. Carriers should be looked for.

The *treatment* of these conditions is briefly as follows: Any patient showing any signs of a suspicious infectious disease is immediately sent to one of the small isolation rooms in the building (these isolation rooms are a part of an antique ward system); bichloride sheets are suspended; gowns are in readiness for physicians and nurses; utensils, etc., are set aside for the patient's use and all excreta, sputum, etc., are disinfected before leaving the room. As soon as the patient is ready for transfer, the disease having been cured, he is given a disinfectant bath and supplied with new underclothing and the room with all of its contents is disinfected with formaldehyde. The laundry, particularly during the course of infection, should be placed in a disinfectant solution and kept adjacent to the room; this, however, should be again disinfected in the laundry sterilizer before being washed with the general laundry.

Especial attention should be paid to the source of infection and the wards from which the patient came. If necessary, quarantine the ward.

Conclusions.—1. Infectious diseases are prone to occur in all intra-mural insane. The proper prevention and subsequent treatment of these diseases will not only alleviate the sufferings of many who are not responsible for the dependent state, but, at the same time, is quite a civic and essentially economic saving.

2. Every institution, it matters not how large or small, should make an effort to safeguard the general health of its inmates by insisting upon sanitary and hygienic measures being not only installed but actually operated.

3. All institutions for the housing of insane should have an isolation section, preferably an isolation building.

4. The resident medical staff of such institutions should have free access to consultation with experts in this particular line of diseases. The Philadelphia Hospital for the Insane is exceptionally fortunate in having access to the trained experts in this line of work in the Bureau of Health.

5. Early isolation and quick diagnosis, appro-

priate treatment, including sanitation, disinfection, etc., will prevent the spread of all infectious diseases, unless their source of infection is a general one such as milk, water and so on.

6. In cases of infectious diseases occurring in institutions, it behooves superintendents working in conjunction with the Board of Health to ascertain if possible the avenue of infection and the correction of the same. Vaccines in general for the prevention of diseases should be recommended as a harmless preliminary prevention of some of the most fatal disorders.

7. In the actual handling of a case of infectious disease one should adhere as much as possible to the brief outline under the heading of "Treatment."

8. The greatest adjunct in the prevention and treatment of infectious diseases of the insane is a progressive medical staff, preferably of young, enthusiastic graduates, well versed in the diagnosis and treatment of physical diseases, with free access to laboratory facilities and free consultation with men experienced in this line of work.

THIRTY-FOURTH AND PINE STREETS

LIME THERAPY OF DIABETES.

PRELIMINARY COMMUNICATION.

BY MAX KAHN, M.D., PH.D.,

AND

MORRIS H. KAHN, M.D.,

NEW YORK.

(From the Chemical Laboratory of the Beth Israel Hospital.)

IN a number of metabolism experiments conducted on diabetic patients, we have found it an invariable rule that there is a negative calcium balance. With the onset of acidosis this calcium loss increases so that high figures for calcium excretion will be obtained; but it is not only characteristic of the acidosis stage. Diabetes is characterized, throughout its course, by calcium loss. We will here quote a passage from Von Noorden's "Metabolism and Practical Medicine":

"A very important and interesting question is whether this diminution in alkalinity (in diabetic acidosis) is due only to increase of acid, or whether it may also be due to the loss of alkali in diabetic acidosis; the ash still bears the normal relation to the nitrogen (Magnus Levy). Nevertheless there is a diminution in calcium. Several observers (Bocker, Neubauer, Toralbo) long ago found more calcium in diabetic than in normal urine. Van Ackeren, in Gerhardt's wards, was the first to carry out a complete experiment upon the balance of inorganic constituents in a severe case of diabetes. In 1893, I (Von Noorden) made the following observations but did not publish them: The patient excreted far more phosphorus, calcium, and magnesium in his urine and feces than he took in his food. . . . It was concluded that bone was being disintegrated. . . . The loss of calcium in diabetic acidosis was shown by some experiments of Gerhardt and Schlesinger. . . . When the daily intake was 0.81 gm. of calcium, and the diet was constant, a healthy man excreted 0.62 gm. calcium and a diabetic patient excreted 1.127 gm. calcium. The results obtained by Von Limbeck, Tenbaum, and Moraczewski agree with those of Von Ackeren, Gerhardt and Schlesinger. Dengler showed that the administration of calcium can stop the loss of calcium in diabetic acidosis for some time."

Towles stated that generally, there is a calcium loss found in diabetes.

In certain experiments which one of us (Max Kahn) carried out on rabbits (in collaboration with Dr. Wm. Salant), it was noticed that animals which had developed glycosuria upon caffeine administration, ceased to excrete glucose in the urine when calcium was administered intravenously. The development of glycosuria, it was found, could be prevented by the simultaneous administration of lime with caffeine. In the literature there appeared synchronously several communications from various pharmacological laboratories, in which it was reported that adrenalin glycosuria and nicotin glycosuria could be prevented or stopped by administration of calcium salts.

In a number of rabbits to which sodium tartrate had been administered, glycosuria developed. In the literature it has been reported that citrate and oxalate may induce the appearance of sugar in the urine, and the phenomenon has been explained on the basis of a calcium abstraction from the body; for it is known that these salts precipitate the lime salts out of solution.

Marquis states that there is evidently a physiological loss of lime during pregnancy, manifested by the looseness of the pelvic articulations; if it reaches a pathologic state there is pain in the symphyses, and this he regards as the first stage of osteomalacia, believing that this degree of osteomalacia is quite common; in the second phase there is considerable pain in the bones and walking is difficult, but the pelvis is not deformed. The third stage in which the pelvis is actually deformed, is the only form of the affection recognized by other authors to date, and this is why the prognosis of osteomalacia is generally considered so grave. Examination of the proportion of lime in the blood is a reliable method of determining the condition in regard to lime waste. In two typical cases described in detail, the blood contained 0.12 parts per thousand lime in one and 0.162 parts in the other, instead of the normal average of 0.052 parts for the pregnant woman. The proportion of lime in the blood has always paralleled the severity of the osteomalacic disturbances in his clinical experience. The disturbance in osteomalacia is a decalcification while in rachitis it is more impossibility of recalcification. The decalcification in pregnancy is probably due to some disturbance in ovarian, suprarenal, or similar functioning, with a predisposition afforded by frequently repeated pregnancies and deficiency of lime in the food.

If the above communication of Marquis is carried in mind when one reads the report of the researches of Geelmuyden, one sees some connection between the diabetes of pregnancy and the calcium loss which is characteristic of the period of child bearing.

Geelmuyden comments on the connection between the functioning of the female internal genital organs and carbohydrate metabolism, saying that glycosuria develops regularly in about 10 or 12 per cent. of all pregnancies. Some have encountered it in 40 per cent. Usually lactose is the sugar in the urine in this benign pregnancy glycosuria, but it may be grape sugar or both. The proportion of sugar in the urine may be so large as to suggest severe diabetes with acidosis. Differential points are its onset first during pregnancy, its independence of carbohydrates in the diet, and the absence of polyuria and excessive thirst. He has known

instances of these latter symptoms, polyuria, thirst, and pruritus occurring with unmistakable pregnancy glycosuria. Knowledge that the urine before pregnancy was free from sugar is a great help. Also the findings that the acidosis does not fluctuate with the intake of carbohydrates. Normal or subnormal proportion of sugar in the blood sustains the assumption of the benign form.

Certain observations have been made regarding diabetic lipemia that are interesting. Klemperer states that in this condition the blood contains much cholesterin and lecithin, which originate from the subcutaneous fat. The fat of the viscera is unchanged. The lipoids enter the blood because of the breakup of the body cells. Once in the blood they attempt to regenerate the impaired cells. In brief, diabetic lipemia represents a mobilization of the cell lipoids to form new cells. This procedure enables us to understand certain results of therapy, particularly of severe cases. Albumin of the diet results in a splitting up of all albumin, which is accompanied by lipoid escape. Hence the observance by the patient of fasting days, vegetable days, and in general a low protein diet goes far to antagonize the extreme tendency toward the breaking up of the cells.

Drennan draws the following conclusions as to the pathogenesis of diabetic lipemia. (1) The lipemia of diabetes mellitus is due to the abstraction of calcium salts from the lipoid circulating in the blood; (2) This abstraction is an attempt on the part of nature to neutralize the organic acid which results from the imperfect oxidation of the sugar in the body, fat in the blood being the lesser of two evils. Fat embolism may result in the lungs, but may exist quite extensively without causing serious symptoms; (3) The indications in diabetes would be an increased administration of calcium salts, in the one case sufficient to neutralize the acids and to unite with the neutral fat, and in the other case sufficient to unite with the neutral fat.

In a communication made a few years ago, Von Noorden summarized the pathogenesis of diabetes as follows: Von Noorden states that the liver is evidently the source of sugar production, and that this function is controlled by the pancreas and suprarenals—the pancreas inhibiting sugar production and the suprarenals stimulating it. The pancreas in turn is under the control of the thyroid, the secretion of which has an inhibiting action on the functioning of the pancreas as is shown in the increased tendency to glycosuria and thyroid hyperfunctioning. After thyroidectomy, the pancreas exerts such a strong inhibitory action on the liver that it is almost impossible to induce glycosuria The hypopthysis cerebri seems to have the same action in the pancreas as has the thyroid; with tumor of the hypophysis there is remarkable tolerance for large amounts of sugar. The suprarenals are under control of the sympathetic nervous system and are very sensitive to the action of certain toxins. Formerly it was assumed that the glycosuria resulting from puncture of the medulla ("sugar puncture") was due to direct stimulation of the liver from the central nervous system, but recent research has demonstrated that this stimulation is transmitted by the left sympathetic nerve and at first to the left suprarenal, whence the stimulation is forwarded to the right suprarenal by the connecting nerves. If the left suprarenal is cut off from the left sympathetic nerve, no glycosuria follows the sugar puncture. Puncture of the medulla stimulates the suprarenals to greater secretion, and this secretion in turn stimulates the liver to excessive output of sugar. A number of toxic influences act in the same way, partly by the influence on the sugar center in the medulla, partly by the stimulation of the sympathetic nerve or the suprarenals thus causing exaggerated functioning which entails overproduction of sugar in the liver. These facts, V. Noorden says, explain the influence of the central nervous system on the intensity of diabetic glycosuria and show the necessity for studying each individual case with special care, and the importance of warding off emotional stress and injurious nervous and toxic influences.

McCallum and Voegtlin found that after parathyroidectomy there is a decrease in calcium content of the tissues and blood; and that the symptoms disappeared when calcium was administered.

Underhill and his collaborators performed thyreoparathyroidectomy upon five dogs. In two they gave injections of 30 per cent. dextrose solution subcutaneously and two solutions of calcium lactate at the time when hypoglycemia became marked. The conclusions which they drew are:

1. Hypoglycemia resulting from thyreoparathyroidectomy is neither the cause nor the effect of the accompanying tetany; for although dextrose injections restore blood sugar content to normal, such injections have little influence on tetany. Moreover the condition of hypoglycemia precedes that of tetany. It is therefore suggested that the removal of the thyroid and parathyroid give rise to two distinct effects, one being manifested upon the blood sugar regulating mechanism, causing hyperglycemia, the other acting upon the nervous system producing tetany.

2. Calcium appears to be intimately associated with both effects, for injections of calcium lactate will temporarily restore blood sugar to normal and also abolish tetany for a time.

3. Calcium may play an important rôle in maintaining the equilibrium of the blood sugar regulating mechanism during normal life.

Hyperglycemia which is so characteristic of diabetes is also present in other conditions. The following paper by Hopkins is interesting:

According to Hopkins in health a moderate rise in blood sugar (0.14 to 0.15 per cent.) occurs after feeding 100 gm. of glucose, reaching its height in from one-half to two hours and quickly subsiding. There is no constant blood sugar level at which sugar appears in the urine. Evidently absorption after rectal and subcutaneous injection is slower than after feeding by the mouth; however, owing to the discomfort produced by the former methods this series is too limited to permit of definite conclusions in regard to this point. In a case in which a disturbance in carbohydrate metabolism exists there may be a normal sugar concentration associated with a most pronounced alimentary hyperglycemia. In diabetes, alimentary hyperglycemia is pronounced, the height of the sugar level appearing at any time from one-half to three hours after the ingestion of glucose, and the duration being more prolonged than in other conditions. Pancreatic, nephritic and pituitary cases all furnish very high figures after feeding glucose, the duration lying between that of normal and of diabetic patients.

A moderate hyperglycemia occurs in many high pressure nephritic cases, and frequently in those with low pthalein elimination. In most cases of nephritis with low pressure the blood sugar is nor-

mal. Edema and hepatic congestion do not influence blood sugar values, though the rôle they may play in alimentary hyperglycemia, which is pronounced in nephritis, Hopkins says, he is not prepared to say at this time. A rise in blood sugar occurs in pneumonia and may be present in the absence of fever. It is apparently uninfluenced by blood pressure, leucocytosis, or renal involvement. Hyperglycemia occurs quite constantly in apoplexy, typhoid and tuberculosis, in the presence of fever, and in some cases of cancer. The test, simple and accurate, is a practical method for early diagnosis and control of dietary therapeusis.

Now it is known that in pneumonia there is a calcium loss from the body and it has been recommended that this disease be treated by calcium administration. The French school of physicians has observed a constant loss of calcium in tuberculosis, which they call "demineralization." It is curious to observe hyperglycemia in both of these diseases.

We have endeavored to touch in the above superficial review on the relations of lime to hyperglycemia. It seems as if the organic lime combination in the various glands of the body seems to influence the glucose production. Thus in the liver the calcium seems to functionate as an aid to glycogenbiosis, and a lack of the calcium salts seems to induce a glycogenolysis.

We wish now to report the result of treatment of several cases of diabetes on the theory above enunciated. We shall, in this preliminary communication, cite one case as an example.

The patient, a middle-aged woman, was excreting on a standard diet, from 90 to 115 grams of sugar daily. Upon treatment with lime, the diet remaining the same, in a manner to be subsequently reported, her glycosuria fell in less than ten days to less than 10 grams of glucose per day. The glycemia ran a parallel course.

We hope soon to make a complete report of the results of our investigations.

TREATMENT OF OPIUM OR MORPHINE ADDICTION.

By S. T. RUCKER, M.D.,

MEMPHIS, TENN.

Almost every drug in the materia medica has been used or recommended to treat opium or morphine addiction. Belladonna and hyoscyamus were early used and found favor with some physicians, and these drugs and their alkaloids are still relied on to lessen the pains and suffering a patient goes through when the opiate is discontinued entirely. Some ten years ago I tried out thoroughly these drugs in treating opium-morphine addiction and found them uncertain and unsatisfactory. I soon abandoned their use, except that of atropine in the after treatment.

The Harrison Narcotic Law having caused a largely increased number of "drug-users" to apply to physicians for relief, I feel it an opportune time to offer to the profession an improved method of treatment, based on rational procedure, the results of which have been uniformly good. The horrors and intense suffering incident to discontinuing the use of opium or morphine are eliminated. The patient is kept in bed, asleep or drowsy for two days and a night, after which a fairly rapid convalescence takes place and he is sent home well.

The habitual use of opium or morphine lessens activity of the secretory and excretory organs, inhibits intestinal peristalsis, and disturbs the process of metabolism, hence diaphoretics, diuretics, and purgatives are indispensable in treating the withdrawal symptoms. My treatment is divided into (1) preliminary, (2) special, and (3) after-treatment.

1. When a patient presents himself for treatment a conference is had with him to ascertain something of his character, motives, and the amount of drug used. He is examined physically and a laboratory examination of the blood and urine is made. If he is using 2 gr. or less of morphine per day, and his condition is good, he is given purgatives for two or three successive nights and an electric light bath every day, and is put to sleep the third or fourth day after he enters for treatment. If a large amount of morphine has been taken for years the preliminary treatment is extended to one or two weeks, according to the condition and needs of the patient. He is given a purgative of 5 to 10 gr. calomel and soda and two or three pills containing aloin, strychnine, and belladonna, at about 8 P.M every other night, the electric light bath being given every other day. The drug is also reduced every other day. If the daily dose has been 10 or 15 gr. of morphine, he is reduced to 6 or 7 gr. in the first cut, then, say, 1-gr. reduction until about 2 gr. are reached.

2. Then the special treatment may be given, which is carefully carried out as follows: On the afternoon preceding the special treatment, 10 gr. calomel and soda, 10 gr. compound jalap powder, and two or three pills containing aloin, strychnine, and belladonna are given at 5 P.M. The last dose of morphine is given not later than 6 P.M. the same day. No supper is given. At 8 P.M I give 15 gr. calomel and soda, 10 gr. compound jalap powder, and three of the aloin, strychnine, and belladonna pills. The patient is left alone until 6 A.M next day (first day of special treatment), when Epsom salt or some active effervescing saline is given in a tumbler of water. The patient is given a warm tub bath about 6.30 A.M., and put to bed in a different room from the one previously occupied. The room vacated and also the clothes of patient are carefully searched some time during the day for any drug he might have secreted. At 7 A.M. a dose of 30 to 35 gr. of trional is given, followed by a glass of hot sweet milk. At 10 A.M. and 2 P.M. the same size dose of trional is given, if the patient is awake, followed by the hot sweet milk. If the patient is asleep when the times for the second and third doses of trional come, one should wait until he awakens himself, then repeat the trional powder.

The patient is kept in bed, shades down and room darkened, and a special nurse assigned to care for him and give treatment for two or three days, or longer if necessary. The nurse is instructed to keep things quiet in the room, to give the patient water or milk when he is wide awake, and to feel his pulse occasionally. No one is allowed to see him during the special treatment except the doctor and nurse.

At 6 A.M the second day a 90-gr. dose of sodium bromide is given in a tumbler of water. At 10 A.M. and 2 P.M. another dose of 60 to 90 gr. of sodium bromide is given in a tumbler of water if the patient is awake. The patient is kept in bed the second day, and the room is kept darkened and quiet. Physician should go in to see how patient is doing at least twice a day.

At 8 P.M the second night 5 gr. of calomel and soda and two or three aloin, strychnine and belladonna pills are given, with 7 or 8 gr. of veronal.

3. At 6 A.M. the third day after treatment is begun with a saline in a tumbler of water. A tonic prescription of fluid extract cimicifuga 6 drams, avena sativa 9 drams, and aromatic elixir enough to make 3 ounces, one teaspoonful in water at 7 and 10 A.M., and 2 and 5 P.M. I also give hypodermically strychnine nitrate 1/30 gr., and atropine sulphate $\frac{1}{100}$ gr. at 8, 12, and 4 o'clock. These drugs are given in reduced dosage for two or three weeks. The patient is allowed to get up on third day, if he feels like it. Baths are begun and continued every other day. Light, regular meals are allowed on the third day and increased as the patient's appetite gets better. As a rule, the patient improves rapidly and soon feels better than when taking opiates.

Drug users can stand large doses of purgative medicines. Calomel will not salivate when combined with other purgatives and followed by a saline to properly work it out of intestines. The gums may become a little tender, but this will pass away in a few days. Drug patients will also tolerate large doses of hypnotics and will take 90 to 100 gr. of trional (in three doses) during the first day of the special treatment, without bad effects. Anuria occurred in one patient, but I believe this was due to the patient's condition, rather than to trional. The electric light bath is extremely useful; it is a powerful stimulus to the general circulation of the blood and increases the action of the skin and kidneys. It is also calmative to the nervous system and induces sleep. I have taken patients off of morphine without giving the electric light bath, but they do so much better with it that it has become part of my routine treatment.

Complications and suffering, if any, occurring during or after the withdrawal period are due either to neglect in strictly carrying out the plan of treatment, or to some inter-current bodily ailment. In some patients minor aches or pains may be caused by a bad tooth, a neuralgic diathesis, and intestinal stasis. Such conditions, when they arise, must be treated symptomatically and by such remedies as the judgment of the physician may prompt. Some patients will go through treatment without complaint and they seldom ask for an opiate.

The psychic side of treatment must not be ignored. There is marked psychic deterioration in some drug users. They develop a weak will, a lack of self-confidence, a fear of suffering, and a tendency to falsify. Ethical ideas depreciate, and the moral standard is lower. This class of patients should be taught how to discipline and control the emotions, how to re-educate confidence and will-power, and be urged to cultivate the ability to endure bodily ills and discomforts like persons who do not use opiates, instead of resorting to drugs to relieve every little ache or pain.

Finally, I will say that while this method of treatment is safe and successful when properly carried out, like other good things, it is capable of producing harm in the hands of the careless or ignorant. The treatment should be administered in hospitals and sanatoriums where nurses, baths, and other necessary facilities are available, and by physicians who will take the time to familiarize themselves thoroughly with the method of treatment and who will take the pains to see that every detail of treatment is carefully carried out.

GOODWYN INSTITUTE.

Medicolegal Notes.

Medical Services—Evidence of Balance Due.—A practising physician sued the defendant for an alleged balance due him for professional services. It was admitted by the defendant upon the trial that he had visited the defendant 123 times; that the charge for each visit was, by arrangement with the plaintiff, fixed at the sum of $2 per visit. It was conceded by plaintiff that $236 had been paid him, leaving a balance of $10 due. The defendant testified that, "I believe in all I have paid him around $290," but he could give no reason for such belief. He also testified that, when he ceased visiting the plaintiff's office he "thought he owed him probably $10 or $15." He said that it ran along about a year, and then he got a bill for $60, upon which he paid plaintiff $50, and upon consultation with his employers, to whom the plaintiff had written letters, was told by them that "they considered the bill was well paid." This was held to be corroborative of the plaintiff's claim that there was still due and owing him the sum of $10, and there was no testimony from which it could be reasonably said that plaintiff's bill was incorrect. The plaintiff should therefore have had a judgment for $10.—Bedell vs. Malloy, New York Appellate Division, 153 N. Y. Supp. 167.

Privileged Communications—Physical Examination—Physician Not Called by Patient.—In an action for personal injuries received in a railway wreck it appeared that the plaintiff sent its own surgeons to take care of the injured and to carry them to a hospital. There was some evidence tending to show that the plaintiff was not given that care and consideration which he was entitled to receive while he was at the scene of the wreck. To rebut this evidence the railroad offered to prove by its surgeons that they examined the plaintiff at the time, and that his wounds had been dressed and properly treated, and that this was all that could have been done under the circumstances. At the instance of the plaintiff the trial court excluded this evidence from the jury. This was affirmed on appeal. The Mississippi statute regarding privileged communications provides: "All communications made to a physician or surgeon by a patient under his charge . . . are hereby declared privileged." "It is not necessary," the appellate court said, "that the communication should be made by words in order to make it privileged. There is no more sacred relation of confidence than the relationship of physician and patient, and it was, in our opinion, the intention of the Legislature to close the lips of the physician concerning any and every thing he knows about the patient by oral communication or from a physical examination of the patient. . . . The statutes of the several States vary in the language employed, but in our view they were all designed to accomplish the same purpose. Our statute in protecting the patient makes privileged 'all communications,' and we think it would be absurd to say that what the patient says to the physician is privileged, but what is communicated to the physician by his expert examination and exploration of his patient's body is not privileged. The oral communications are usually of little importance, but the physical examination is always of prime importance. The fact that the physicians in the present case were not called by the plaintiff, but were sent by the defendant to examine or treat plaintiff, does not change the legal aspect of the case. The physicians were acting in their professional capacity, and the plaintiff was their patient, and all communications to their professional senses are privileged, and the physician, however willing he may be to violate the condence of his patient, will not be permitted to do so by the wise provisions of the statute. In the light of such authorities as we have been able to find, the overwhelming weight are in accord with this view of the law."—Yazoo & M. V. R. Co. vs. Messina, Mississippi Supreme Court, 67 So. 963.

Duty to Patient—Negligence of Patient.—A physician contracts with his patient that he has the ordinary skill of members of his profession in like situation, that he will exercise ordinary or reasonable care and diligence in his treatment of the case and that he will use his best judgment therein. On the other hand it is the duty of the patient to follow the reasonable instructions and submit to the reasonable treatment prescribed by his physician or surgeon. If he fails in his duty, and his negligence contributes to the injury, he cannot maintain an action for malpractice against his physician or surgeon, who is also negligent in treating the case.—Merrill vs. Odiorne, Maine Supreme Court, 94 Atl. 253.

SPECIFIC PROPHYLAXIS AND TREATMENT OF PNEUMONIA.

LOBAR pneumonia is one of the most familiar of the diseases with which we come into contact and it is one of the best known. Its etiology and pathology are well understood and the bacteriology has been very thoroughly investigated. In spite of these facts its treatment is still very unsatisfactory. The course in a typical case of the disease indicates an infection, local as a rule though sometimes general, against which the body develops an immunity which is able to bring about a sudden termination of the infection if not a destruction of the invading organisms. The mechanism of the crisis is, however, unexplained and attempts to produce it artificially have hitherto been unsuccessful. The pneumococcus is the most vulnerable of the Gram-positive organisms when exposed to the action of bactericidal agents *in vitro* and yet it often apparently remains unaffected by materials which we are able to introduce into the body. Many forms of treatment have been devised but the nature of the disease is such that it is extremely difficult to judge accurately of the value of any one of them. The virulence of the attack varies so much from year to year or even from month to month that results obtained in any restricted series of cases are worthless when applied to the disease as a whole. This is best evidenced by the manner in which widely heralded methods of treatment have quietly dropped out of notice within a year or two of their introduction. Since the crisis is obviously an immunity reaction the principal attack upon the problem in late years has been made by the immunologists and some definite advances have been noted. Cole and his co-workers have shown that the pneumococcus may be divided into groups which give different immunity reactions and different mortality statistics and furthermore that the pneumococcus which normally inhabits the mouth belongs to a nonvirulent type. But the use of serums and vaccines has as yet yielded no striking results.

The subject of pharmacotherapy and preventive inoculation has lately been the object of study by Sir Almroth E. Wright who has been investigating the disease as it occurs among the natives of South Africa.* He had unusual facilities in studying the disease as it occurs among the native Africans working in the mines, who are extremely susceptible to it. The work was undertaken under the auspices of the Witwatersrand Native Labor Association and extended over the better part of three years. He naturally, at first, directed his attention to ethylhydrocuprein hydrochlorate, a drug whose specific action against the pneumococcus *in vitro* was noted in these columns in the issue of Oct. 9. He found, indeed, that the blood of patients who had received the drug showed an increased bactericidal effect upon the pneumococcus but that when it was administered to patients suffering with pneumonia it was "either inefficacious or doubtfully efficacious." In addition there was a certain amount of danger from the toxic action of the drug upon the eye. He thereupon devoted his attention to the action of vaccines administered not only after the onset of the disease but also as a prophylactic measure. After determining that the disease was, in fact, due to the pneumococcus, great difficulty was experienced in the attempt to find some method of examination whereby it could be discovered how the patient was reacting to the inoculation. Estimation of the agglutinating and the bactericidal power of the serum failed to give any information of value while the opsonic index varied so much and in such an irregular fashion that it also could not be used. An estimation of what Wright calls the phagocyto-bactericidal power of the blood proved to be impracticable under the conditions of the research, and he was therefore forced to go ahead and decide the size and frequency of the doses in an empirical manner and to estimate the effects from the mortality and morbidity statistics. In the treatment of the disease, when fully developed, he had almost exactly the same mortality in 159 cases as he had in the 149 control cases treated in the usual way. In this connection, however, there are some exceedingly interesting figures presented as to the results of vaccines given presumably during the incubation period of the disease. In groups receiving doses up to 1000 millions of pneumococci, in the first four days after inoculation, 2500 inoculated had an incidence rate of 0.52 per cent. and a death rate of 0.16 per cent., while 750 controls had an incidence rate of 1.4 per cent. and a death rate of 0.84 per cent. "In other words, the uninoculated had an incidence rate nearly three times, and a death rate five times greater than the inoculated." In larger doses the inoculated seemed to suffer more than the uninoculated which apparently showed the existence of a negative phase. This certainly shows that the vaccine had some beneficial effect upon the infection and yet the practical application of the observation is limited, for it is almost always impossible to determine when a patient is in the incubation stage of a pneumonia. Nevertheless the vaccination of those exposed to the disease might have favorable results. It is not a rare thing for the attendants of a patient suffering with pneumonia to develop

*On Pharmacotherapy and Preventive Inoculation Applied to Pneumonia in the African Native. By Sir Almroth F. Wright, M.D., F.R.S. Price, $2.00 net. New York: Paul B. Hoeber, 1915.

the disease and Dochez and Avery have shown that such attendants frequently carry in their mouths a pneumococcus of the same type as that infecting the patient. There might very well be a distinct indication for the use of vaccine under such circumstances.

Wright's most striking results were obtained by the use of pneumococcus vaccine as a prophylactic measure. He was fortunate in having a very large mass of material and his observations extended over a considerable period of time so that he is justified in drawing definite conclusions. The experiments are divided into sections so that all the figures cannot be presented here and we shall give only sufficient to indicate the nature of the results he obtained. During a period of three or four weeks following vaccination, 5963 inoculated natives showed a morbidity of 2.6 per cent., and a mortality of 0.83 per cent., while 5671 uninoculated gave a morbidity of 3.5 per cent and mortality of 1.53 per cent. When these cases were followed for a longer period of time it was seen that this immunity was of a short duration, for after the end of the second month following inoculation the case incidence among the inoculated and uninoculated was practically the same. This corresponds with the clinical observation that one attack of pneumonia does not protect against another. Curiously enough, after the introduction of prophylactic vaccination there seemed to be an improvement in the condition of both groups of natives so that even the uninoculated derived some advantage from the procedure. Thus he gives the following figures for the workers of one mine. In 1911 with a population of 10,426 none of whom were inoculated there was an incidence of 4 per cent. and mortality of 0.97 per cent. In 1912 about 50 per cent. of the 12,549 natives were vaccinated. In this year the incidence rate was 0.86 per cent. for the inoculated and 1.7 per cent. for the controls. The following year the population reached 15,284 of whom about 92 per cent. were inoculated, and among these the incidence rate was 0.6 per cent. while 3 per cent. of the controls developed pneumonia. It is easy to make the objection that Wright's results will prove of practical value only under certain special conditions and that to some extent is true. Surely one would hardly propose to vaccinate the whole population of the city on the first of January in each year. Nevertheless he has shown us that vaccines will do something toward developing an immunity against the disease and further extension of this work may increase their value in its treatment.

THE AUTOPSY, WAR, AND TUBERCULOSIS.

It is eminently characteristic of the German scientific spirit that an attempt should be made to transport the methods of the autopsy room to the battlefield and military hospital—as if those who died for their country might yield a further sacrifice or service, this time to humanity at large. The victims of war are generally those who are cut down in the bloom of life, who die as the result of severe injuries or of rapidly terminating acute infectious diseases. Aschoff has suggested that anatomical data of considerable value may be obtained from the autopsies of those who die in the strength of full manhood—particularly with reference to the normal weight of the individual organs. J. G. Mönckeberg (*Zeitschrift für Tuberkulose*, May, 1915) finds a still greater value in these autopsies as a means of determining the presence or absence of latent pathological processes. In his own investigations he has confined his attention to tuberculous lesions. In 27 out of 85 cases (31.76 per cent) he found evidences of tuberculosis, either active or healed. The above 27 cases comprised 22 German and 4 French soldiers and 1 Belgian soldier, of ages varying from 21 to 43 years. In five of these cases tuberculosis was to be regarded as the cause of death, but in the remaining 22 it was an accidental finding. In three of these there were recent or fresh lesions. In most of the cases the seat of the disease was the right lung.

A question of considerable practical importance arose in the study of the above cases, namely, to what extent are latent tuberculous lesions liable to become active ones under the stresses and privations of military life? No evidence was forthcoming that any of the latent lesions in the above cases had become active, whereas the five recent cases of tuberculosis concerned individuals who were tuberculous at the beginning of their military service, and in whom the disease made rapid progress and terminated fatally in a short time. This last fact, emanating from an authentic source, is one of more than mere scientific interest: it shows how under the stress of national necessity even tuberculous individuals are enlisted to fight the battles of their country! The history of the following case requires no comment: A 24-year-old farmer who had suffered from an intestinal trouble since July, 1913, was operated upon in January, 1914, and there was demonstrated the presence of tuberculosis of the cecum and miliary tuberculosis of the peritoneum. Nine months later he was enlisted as a reservist and in one month more was admitted as a patient to a military hospital and died a little over two months later. Autopsy revealed the widely disseminated and extensive lesions of a chronic general tuberculosis.

CIRCUMCISION OF THE TONSIL.

Circumcision of the tonsil signifies its complete detachment from the pillars and the breaking up of other adhesions that may be found about the tonsil. Dr. F. G. Murphy discusses this operation in the *Journal of the Iowa State Medical Society*, August, 1915. He points out that circumcision of the tonsil is indicated in the case of those who have septic tonsils and who are not physically able to withstand enucleation or who hesitate to do so. The results have been equally favorable in hypertrophied tonsils. The reasons for this operation are given at some length, and it is stated that with the tonsils entirely separated from the pillars and when these pharyngeal muscles milk the tonsil crypts, there can be no retention cysts and consequently no chronic lacunar tonsillitis. If, as

MacLachlan thinks, peritonsillitis is likely to come from extratonsillar origin, there is little probability of an attack of quinsy occurring when the anterior fossa and supratonsillar fossa are freed from all adhesions. Murphy further draws attention to the fact that for the past few years the trend of the profession has been toward the total extirpation of apparently non-essential organs such as the gall-bladder, appendix, and tonsils. However, if it were possible to render the gall-bladder and the appendix permanently inoffensive, no surgeon would advise their removal. After pointing out the dangers of total extirpation of the tonsil, the writer goes on to say that it is safe to state that three times more people will submit to circumcision of the tonsil than will submit to enucleation. He concludes that, as it is now conceded by the profession that the infection in appendicitis, cholecystitis, pancreatitis, and ulcer of the stomach is frequently of tonsillar origin, therefore the circumcision of the tonsil, being an operation which causes so little inconvenience to the patient, should find ready acceptance as a prophylactic measure.

Alcoholism in France.

Without necessarily being definitely aligned on either side of the subject, one is led to believe that the present war is a trial on a large scale of the popularity and value of alcoholic liquors. Already France has put the ban on absinthe, Russia on vodka, England looks with disfavor on spirits, while Italy has begun to limit the distribution of wine. The medical men of England were divided last winter over the daily allotment of spirits to the soldiers in the trenches (the so-called "rum ration") and many were the heated arguments and even personalities which filled the columns of the medical press over this subject. On Feb. 12, the French Chamber of Deputies passed a clause prohibiting the manufacture and sale, wholesale or retail, of absinthe and similar beverages. Naturally the French medical profession took sides on the question. The Academy of Medicine of Paris debated it at length and finally recommended in a series of resolutions the stopping of the sale of all beverages of high alcoholic content. These resolutions were so worded as to include liqueurs, brandies, and strong wines. They also recommended a heavy tax on all liquors containing over 15 per cent alcohol. It is noteworthy that these resolutions contain nothing which might be construed as disapproving of the use of light wines; in fact, the general opinion of the members of the Academy seemed to be that the amounts of these furnished the soldiers might be increased. Beer, cider, and similar drinks were also not restricted. The consumption of light wines, as every one knows who is at all conversant with the customs of the Latin races, is very general among them, wines being served with meals in lieu of water. These wines are usually of a very low alcoholic content and are often rendered still further innocuous by dilution with water.

A Warning.

We have several times called attention in these columns to the collection of subscriptions for the Medical Record or *The American Journal of Obstetrics and Diseases of Women and Children* by unauthorized persons. There is apparently an organized band of these rascals working the cities and larger towns in many sections of the country. Their scheme, or one of their schemes, is to represent themselves as an association of indigent students who are given free tuition in a medical college in return for a certain number of paid subscriptions, new or old, to either or both of the abovementioned journals. They thus work upon the sympathies of their dupes who feel they are helping deserving young men to get a medical education, while at the same time they are treating themselves to some of the best obtainable medical literature. We would again warn our present subscribers not to give money for renewals to any but our authorized agents, or preferably to send it direct to the subscription department of one or the other journal. As to the intending new subscribers, we are doing our best to protect them by notifying the police of the States where these gangs of sharpers are working. We would also suggest to our friends that they would be doing a favor not only to us, but, and especially, to their colleagues if they would speak of this matter in their society meetings, cautioning their fellow-members never to pay money for books or for subscriptions to this or any other journal to any but authorized agents of the publishers. By giving such warning they would help the readers not only of this but of other journals, for the subscribers to several of our contemporaries have been defrauded in the same way and by the same persons.

News of the Week.

Red Cross Excluded from Turkey.—The Turkish Government has informed the State Department at Washington that the American Red Cross will not be permitted to send surgeons and nurses to the aid of the Armenian people of the Turkish Empire. The number of Armenians thus far massacred by Turkish soldiers or sold into the harems is estimated at over 850,000.

Medical Deserters.—Among the nine German naval officers on the *Prinz Eitel Friedrich* and the *Kronprinz Wilhelm,* interned at Norfolk, who broke their parole, we regret to say there were two medical men, Drs. Koch and Kronecker. We had hoped the medical profession at least would have come out of this war without dishonor.

Tuberculosis Conferences.—The second annual New England Tuberculosis Conference was held last week at Springfield, Mass., with over 200 delegates in attendance. The opening address was made by Dr. Stephen J. Maher.

The second annual meeting of the North Atlantic Tuberculosis Conference and the annual tuberculosis conference of the State Charities Aid Association will open in Albany on November 4. The meetings will continue four days and will be held under the auspices of the State Department of Health, the National Association for the Study and Prevention of Tuberculosis, and the State Charities Aid Association. Governor Whitman, Dr. Hermann Biggs, State Commissioner of Health, and Mr. Homer Folks, secretary of the State Charities Aid Society, will deliver addresses at the opening meeting.

New York City Death Rate.—During the week ended October 16 there were 1,287 deaths in this city, giving a rate of 11.56 per thousand population, as compared with 1,185 deaths and a rate of 11.07 during the corresponding week of 1914. The real death rate is probably higher than this, for the partion cessation of immigration and the exodus of

Italian and other reservists has brought the population of the city below the estimate upon which the returns are made.

Chicago Death Rate.—During the week ended October 16 there were 583 deaths in Chicago, giving a rate of 12.4 per thousand, as compared with 559 deaths and a rate of 12.2 during the corresponding week of 1914.

Health of the Canal Zone.—Dr. Chas. F. Mason, chief health officer, reports that during the month of August there were 50 deaths in the Isthmian Canal Zone, of which 46 were from disease, giving a rate of 18.26 per thousand, as compared with 16.23 for the month of August, 1914. The rate in Panama City was 29.02 per thousand, as compared with 23.55 for the corresponding period of last year. In Colon the rate was 20.86 for August, 1915.

Deaths from Walking on Railroad Tracks.—In a bulletin recently issued by the New York & New Haven Railroad it is stated that during the past year 5,471 persons in this country were killed while walking on railroad tracks; that is to say, 15 persons lost their lives through this form of carelessness or recklessness every day in the year.

Dr. Bulkley's Lecture on Diseases of the Skin.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley, assisted by the attending staff, will give a seventeenth series of clinical lectures on diseases of the skin in the Out-Patient Hall of the hospital on Wednesday afternoons, beginning November 3, 1915, at 4.15 o'clock. The lectures will be free to the medical profession on the presentation of their professional cards.

Harvey Society Lecture.—The second lecture of this series will be given at the New York Academy of Medicine on Saturday, November 6, at 8.30 P.M., by Prof. A. J. Carlson of the University of Chicago. The subject of the lecture will be "Recent Contributions to the Physiology of the Stomach."

Cornell Medical School.—At the opening exercises of this school, held last week, the Dean, Dr. William M. Polk, delivered the address of welcome to the students. He said that fifty years ago there was practically only one course open to the graduate in medicine, viz., practice, whereas now there are many lines, such as public health and sanitation, the army and navy, research and teaching, as well as medical missionary work, which he regarded as one of the highest of callings. The number of students enrolled at the beginning of this session was 172.

The Elizabeth Steel Magee Hospital in Pittsburgh was dedicated with appropriate ceremonies on Wednesday of this week. Addresses were made by the Rev. David Jones, representing the trustees; Dr. C. E. Ziegler, medical director; the Rev. S. B. McCormick, chancellor of the University of Pittsburgh, and Dr. W. W. Chipman, of McGill University Medical School.

Dr. Henry A. Strecker has been appointed chief medical inspector of the Philadelphia Bureau of Health, in succession to Dr. Charles A. Groff resigned.

Dr. Florence C. Child has been appointed medical inspector in the Division of Child Hygiene of the Philadelphia Bureau of Health.

Dr. A. J. Barker Savage has been appointed superintendent of the new Broad Street Hospital in this city.

Dr. S. P. Beebe has resigned from the medical staff of the New York General Memorial Hospital and from the faculty of Cornell Medical School.

Dr. A. W. Taves has removed to 71 West Eighty-fifth Street, New York.

Dr. John O. Blake has been appointed health commissioner of Baltimore in succession to Dr. Nathan R. Gorter, who has been made a member of the Maryland State Board of Health.

Dr. William G. Spiller has been elected professor of neurology in the University of Pennsylvania in succession to Dr. Charles K. Mills resigned.

Dr. Melvin M. Franklin has been appointed orthopedic surgeon to the Philadelphia General Hospital in succession to Dr. Gwillym G. Davis resigned.

Dr. Ray Lyman Wilbur, professor of medicine, has been elected president of Leland Stanford Junior University. He will assume his new duties on January 1.

General Practitioners and Osteopaths.—Attorney-General Woodbury, in an opinion given to the New York State Educational Department, holds that general practitioners may employ osteopathy in cases where the condition of a patient warrants such practice, but they may not advertise and hold themselves out to the world as osteopaths, unless they are licensed to practice that system.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made on July 14, 1916, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the secretary of the college, Dr. Francis R. Packard, on or before May 1, 1916. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. The successful essay or a copy of it must remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1915 has been awarded to Dr. J. E. Sweet of Philadelphia for his essay entitled: "The Surgery of the Pancreas."

Philadelphia Medical Club.—A reception was tendered on the evening of October 15 to the Surgeons General of the United States public services. Dr. William C. Gorgas, Surgeon General of the United States Army, was unavoidably absent. Rear Admiral William C. Braisted, Surgeon General of the United States Navy, urged the formation of an active reserve force of seven hundred medical men for the United States Navy, all less than forty-five years of age, who should bind themselves for a period of five years' service, and to be trained and ready for duty in case of war. Also he advocated the formation of a reserve hospital corps of five hundred men of high type as nurses, to be trained in naval hospitals together with at least eight hundred women nurses. Surgeon Rupert Blue, of the United States Public Health Service, urged the passage of legislation for the systematic trapping and extermination of rats, with a view to preventing the invasion of bubonic plague. Dr. Judson Daland was nominated for president of the club, Dr. William Duffield Robinson for vice-president, Dr. Wm. S. Wray for secretary and Dr. Lewis H. Adler, Jr., for treasurer.

No Insurance Against Malpractice Suits.—The Ohio State Superintendent of Insurance has ordered the cancellation of policies issued by liability companies to indemnify surgeons in case of loss of malpractice suits. The reason given is that the issuance of such policies is in probable contravention of public policy as permitting insurance against lack of skill or carelessness.

Charitable Bequests.—By the will of the late Charles Fox of Philadelphia the sum of $3,600 is bequeathed to the Methodist Hospital.

By the will of the late Sarah J. Robeson of Philadelphia the sum of $15,000 is bequeathed to St. Timothy's Hospital of Roxborough for the endowment of three free beds, the sum of $3,000 to the Mercer Memorial Home, Atlantic City, for the endowment of a free bed, and $1,000 to the Children's Seashore House at Atlantic City.

By the will of the late Elizabeth Pile of Philadelphia, a residuary estate of about $50,000 is bequeathed to the Pennsylvania Hospital for the endowment of free beds.

By the will of the late Julia Baeder of Philadelphia bequests of $5,000 each are made to the Polyclinic Hospital and St. Luke's Hospital.

Red Cross Christmas Seals.—Two hundred million Red Cross Christmas Seals are now being printed and distributed by the American Red Cross and The National Association for the Study and Prevention of Tuberculosis, according to a statement issued by the latter organization to-day. The proceeds from the sale of these seals will go for the fight against tuberculosis in the communities where the seals are sold. Of this number the New York State Charities Aid Association expects to sell ten million, an increase of more than a million and a half over the sale of last year.

Examinations for Admission to the Medical Corps, U. S. Navy.—The next examination will be held November 15, 1915, at Washington, D. C.; Boston, Mass.; New York, N. Y.; Philadelphia, Pa.; Norfolk, Va.; Charleston, S. C.; Great Lakes (Chicago), Ill.; Mare Island, Cal., and Puget Sound, Wash. Applicants must be citizens of the United States and must submit satisfactory evidence of preliminary education and medical education. The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps and embraces the following subjects: (*a*) Anatomy, (*b*) physiology, (*c*) materia medica, (*d*) general medicine, (*e*) general surgery, and (*f*) obstetrics. The successful candidate then attends a course of instruction at the Naval Medical School, during which course he receives a salary of $2,000 per annum, with allowances for quarters, heat, and light, and at the end of the course, if he successfully passes an examination in the subjects taught at the school, he is commissioned an assistant surgeon in the navy. Full information with regard to the physical and professional examination may be obtained by addressing the surgeon-general of the Navy, Navy Department, Washington, D. C.

Pathological Society of Philadelphia.—At a stated meeting held October 14 Dr. Eugene L. Fiske delivered the Samuel D. Gross lecture, taking up for consideration "The Increasing Mortality from Diseases of the Heart, Blood Vessels, and Kidneys." He pointed out, as a result of careful, painstaking and extensive statistical studies, that while communicable diseases in general, and prominently tuberculosis, have in recent decades diminished in frequency in the United States and exhibited a lower mortality than in the past, the so-called degenerative and recessive disorders, and more especially those involving the heart, the blood vessels, and the kidneys, have increased in frequency and have yielded a growing mortality, when compared both with the past in this country and with existing conditions in the countries of Europe.

National Committee for the Prevention of Blindness.—The annual meeting of this committee will be held at the New York Academy of Medicine on Thursday afternoon, November 4, at 4.30 P.M. Hon. Joseph H. Choate will preside, and the speakers will be ex-President William H. Taft and Dr. George E. de Schweinitz.

Bust of Dr. Battey.—Mrs. Martha Smith Battey has presented the Emory University a marble bust of the late Dr. Robert Battey of Rome, Ga.

The Late Dr. Austin Flint.—At the meeting of the faculty of the Cornell University Medical College held at the college on Friday, October 15, 1915, the following memorial was read and adopted: Austin Flint, M.D., LL.D., Professor Emeritus in the Cornell University Medical College, passed away September 22, 1915, in the eightieth year of his age. A student of Claude Bernard and of Robin, he early achieved distinction. Thus, in 1862, at the age of twenty-five, he discovered a substance in human feces which he called stercorin, recognizing it as a derivative of cholesterin. This discovery was awarded honorable mention by the Institute of France. It did not receive full recognition because of an unfavorable pronouncement by Hoppe-Seyler. However, in 1896, stercorin was again discovered, this time by Bondzynski, and given the name of koprosterin. To Flint, however, working with older, cruder methods, belongs the credit of having first isolated the substance in pure crystalline form.

Austin Flint was one of the greatest teachers of the old school of American medicine. A forceful orator and skilled experimentalist, he was the first in this country to expound the doctrines of the French school of physiology which in his early life was at the height of its renown. Dr. Flint took pride in being of the fifth generation of noted physicians, his great-grandfather and his father having borne the name Austin Flint, a name which outlives him in a surviving son.

We, the faculty of the Cornell University Medical College, with which Dr. Flint was associated during ten years, hereby record our appreciation of this life and beg to tender our sympathies to his family.

Obituary Notes.—Dr. PATRICK WILLIAM CREMIN of New York, a graduate of the College of Physicians and Surgeons, New York, in 1866, and a member of the New York State and County Medical Societies, died at his home on October 17, aged 74 years.

Dr. WILLIAM NOYES of Boston, Mass., a graduate of the Harvard University Medical School, Boston, in 1885, and a member of the American Neurological Association, the Boston Society of Psychiatry and Neurology, the American Medico-Psychological Association, and the Massachusetts Medical Society, died at his home, after a short illness, on October 20, aged 58 years.

Dr. E. S. MCCAIN, deputy State health officer at Brownsville, Tex., a graduate of the University of Texas, Medical Department, Galveston, in 1903, was killed by Mexican raiders at Brownsville on October 18.

Dr. ADOLPH KESSLER of New York, a graduate of the University of Berlin, Germany, in 1855, in

charge of the United States Military Hospital at Baltimore during the Civil War, formerly a member of the Board of Coroners of New York and assistant sanitary superintendent of the Bronx, and a member of the New York State and County Medical Societies, died at his home on October 20, aged 82 years.

Dr. WILLARD K. DYER of Boston, Mass., a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1908, died in a Boston hospital on October 18, aged 64 years.

Dr. WILLIAM MILLER BAIRD of Atlanta, Ga., a graduate of the Bellevue Hospital Medical College, New York, in 1877, died at the home of his son in Baltimore, Md., after a long illness, on October 10, aged 56 years.

Dr. SAMUEL CHASE THAYER of Boston, Mass., a graduate of the Medical School of Maine, Portland, in 1882, died at his home, from pneumonia, on October 11, aged 54 years.

Dr. GEORGE W. PRUGH of Cincinnati, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1875, died suddenly, while attending a reception, on October 12, aged 66 years.

Dr. EDMUND R. BOLDING of Elbing, Kan., a graduate of the College of Physicians and Surgeons, Kansas City, in 1898, died suddenly in Kansas City on October 9, aged 44 years.

Dr. JAMES A. MCGUIGAN died at Philadelphia on October 21, at the age of 69 years. He was graduated from Jefferson Medical College in the class of 1862. He served as surgeon in the United States Army during the Civil War.

Dr. JOSEPH BENSON PARKER, rear admiral and medical director in the United States Navy, retired, died at Philadelphia on October 21, at the age of 74 years. He was graduated from Bellevue Hospital Medical College in the class of 1866. He served as acting assistant surgeon in 1863, becoming assistant surgeon in 1866. Passed assistant surgeon in 1867 and surgeon in 1868.

Dr. EUGENE A. GROVE died of paralysis at Carlisle, Pa., on October 23, at the age of 65 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1870.

Correspondence.

OPPORTUNITIES FOR HOSPITAL STUDY IN PARIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Will you not publish the fact that now is the time for students and doctors with a knowledge of French to come to Paris if they would improve an exceptional opportunity to see and even help in the hospitals?

Professors Tuffier, Pozzi, Brouardel, Robin, Moreston, and all in fact are doing their operating and hospital work with the aid of nurses. All the younger doctors are in the military hospitals and at the front. Any of our men coming to observe hospital work in Paris now would easily work into position as assistants and profit more than ordinarily.

At present I am at the front, but if any of the men coming over will inquire for me at the American Embassy, if I am in Paris, I will be only too happy to guide them into any of the special lines in which they may want to work.

SHERWOOD DUNN, M.D.

PARIS.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WINTER SESSION—ADDRESSES—PRIZES—THE BUDGET, A TAX ON PATENT MEDICINES—COLORED BACKGROUND FOR OPERATING—OBITUARY.

LONDON, Oct. 8, 1915.

WITH October comes the opening of the winter session of our medical schools. So there have been meetings and congratulations among teachers and students, with welcomes to new entrants. These last, it must be observed, are less numerous than usual and there was a corresponding air of depression among the assemblies of the early days of the week, except at the women's school, which was able to boast of an increase. The war is held accountable for limiting the number of entrants as well as for depleting the staffs of men who have gone to the front or otherwise undertaken work for the wounded.

The introductory addresses, at one time so marked a feature at all the schools, have fallen off of late years in the important part they played in the ceremonies, and in some instances have been discontinued—to the regret of not a few old students who took pleasure in renewing acquaintances and partly forgotten associations. Then they afforded a number of persons engaged in medical teaching an opportunity of expressing their views or considering questions relating to the education and training of students that might be attracting attention at the time, as well as offering to the students themselves kindly and practical advice for which scarcely another occasion was available.

At Charing Cross Hospital Dr. Ronald M. Burrows, principal of King's College, distributed the prizes and delivered the address, in which he insisted on the importance of the work of the universities and colleges which loomed larger in the national life than ever before. The army in this war had been officered by university men to the extent of 80 or 90 per cent. Their scientists and also those of the hospitals had placed their brains at the service of their country during this war time and it should be remembered that military successes were as dependent on education as literature or science.

At the Middlesex Hospital there was no formal "introductory," but the distribution of the prizes by Sir Kingston Fowler. The dean read his annual report, which was of a congratulatory tone. A number of beds were reserved for wounded soldiers and the convalescent home had been handed over to the War Office. Most of the staff were engaged in some sort of military service, as were many practitioners, former students, some of them having been awarded honors, but not a few having lost their lives.

Sir K. Fowler said a few words to the students. He told them the place where they could best serve their country was the place to which duty called them. All could not be at the front, but all could help in some way. War was a great sifter and separated men and things that mattered from those that did not matter. Play and work were not antagonistic. The profession had done its duty; many doctors had made great sacrifices. The R. A. M. C. had done magnificently, for Sir A. Keogh, to whom we owe so much for system with military hospitals, foresaw the necessities of such a time as this.

The budget this year, on account of the war, is

necessarily a heavy one and has been anticipated with some anxiety by needy professionals. The increased tax on so-called "patent" medicines might well have been greater. Indeed, most people who have any knowledge of these articles admit that they might be taxed out of existence to the advantage of the deluded purchasers. The only people to lose income would be those who derive it from dishonest pretensions.

Sir Berkeley Moynihan has called attention to the advantage of a green background to operation areas. It is much more restful to the eyes than the white usually found and a full light is, of course, essential. Mr. Hamilton Whiteford reports that for three years his operating theater has been painted a pale French blue, which he finds a great relief to the eyes. Mr. Frank Jeans reports that for five or six years he has used pale blue towels for his operations in private practice, his object being the practical one of distinguishing at a glance his own sterilized towels from those of other people.

The winter session of most of our medical societies has begun work during the week. The obstetrical and gynecological section of the Royal Society of Medicine is postponed until December 9.

Mr. Joseph Smith, J.P., D.P.H., Cantab., died on September 18, aged 77. He was the leading advocate of the rights of the members of the College of Surgeons, the president of the society formed for the defense of those rights, and may be considered its founder. Year after year he presided at the meetings and enforced their claims, with a natural and genial eloquence. He had a large general practice for several years, on retiring from which he became medical officer of health for Guildford, honorary surgeon to the Royal Surrey Hospital, and a magistrate for that county. Withal he will, I think, be most remembered in the profession for his earnest, self-denying work on behalf of the great mass of its members.

Sir James M. Moody, medical superintendent of the Cane Hill Asylum, died suddenly on the 20th ult. He was a recognized authority on psychological medicine and was twice offered a commissionership in lunacy, but preferred the work of a superintendent. He was considered a great organizer and administrator. Many who had served under him received analogous appointments in other asylums. He was knighted in 1909.

Lt.-Col. John Henry Dauber, who died on the voyage to Gallipoli, graduated at Oxford in both arts and medicine (1892-4) and was a Fellow of the Royal College Surgeons of Ireland. He was on the staff of hospital for women and a member of the committee, on which he worked assiduously. He was also president of the Chelsea Clinical Society. He was in the Sussex Yeomanry several years before the war.

Progress of Medical Science.

Boston Medical and Surgical Journal.

October 14, 1915.

1. An Analysis of 308 Cases of Typhoid Fever in Children. K. G. Percy.
2. The Therapeutic Value of Occupation for the Insane. E. L. Haines.
3. The Teaching of Applied Therapeutics at Tufts Medical School. F. H. McCrudden.
4. The Workmen's Compensation Act and the Physician. H. J. Crenon.
5. A Method of Testing Gastric Secretion by the Use of a Self-closing Dredge. A. H. Burgess.
6. Sunshine: Its Neglected Analgesic-Sedative Action. J. Bryant.
7. Neuroma of Ulnar Nerve: Analysis of a Case. J. B. Ayer.

1. Typhoid Fever in Children.—K. G. Percy analyzes 308 cases of typhoid fever which have been treated in the Children's Hospital of Boston since 1913. This series embraces children from infancy through the twelfth year. The author comes to the following conclusions: Typhoid is a relatively common disease in childhood and far more prevalent in infancy than formerly supposed. Symptomatically it is ushered in very much as in adults, with headaches, fever, malaise, and abdominal pain as the most frequent symptoms. In this series and in a large collected series from the literature, the spleen is enlarged in 71 per cent. of all cases, rose spots are seen in 61 per cent., positive Widals are seen relatively early in 88.2 per cent., white blood count is below 10,000 in 73 per cent. The fever lasts an average of twenty-five days. Relapses occur in 11.8 per cent., intestinal hemorrhages in 4.2 per cent., perforation of intestines in 1.2 per cent., complications in 10.6 per cent., and the mortality is 5.3 per cent. Therapeutically, a diet, bland, high caloric, and suited to the individual need of each patient, is most important. Hydrotherapy seems to have a vital place in the treatment of the febrile and delirious stage of the disease. Enemata are essential in a high percentage of cases. Stimulants and other symptomatic drugs are to be used as need arises, for typhoid is a disease, cured not by medicine, but by good nursing, and keen, sensible therapy.

5. Testing Gastric Secretion by the Use of a Self-closing Dredge.—A. H. Burgess calls attention to the fact that of the many attempts which have heretofore been made to find a method of obtaining a sample of gastric contents without the use of a stomach tube, none has been absolutely successful. The failures are due chiefly to the fact that contamination with esophageal and pharyngeal mucus has been found unavoidable. His method consists of the use of a capsule, which is so constructed that it automatically closes as it leaves the stomach, and thus protects its contents from contamination. The author gives diagrams and describes this capsule, a dredge, in detail. He points out that by the use of his method an adequate qualitative examination of the gastric contents is possible without the discomfort to the patient which attends the passage of the stomach tube. With the two smaller sizes it is convenient to use a bit of congo red paper in the dredge to indicate the presence of hydrochloric acid, and to transfer a little of the fluid to a slide with a capillary pipette for microscopical examination. The capacity of the two larger sizes is such that 0.1 c.c. or more of gastric contents is obtained, and with care an accurate titration of the acidity can be made. For this purpose it is convenient to use N/200 NaOH solution in an ordinary burette. By the use of the larger dredges it is possible to carry out, if desired, a study of the variations of acidity in the course of gastric digestion.

6. Sunshine.—J. Bryant points out that the healing power of the sun has been known for countless ages. Modern scientific application of this knowledge is, however, limited. Solaria are numerous enough, but there is little attempt to get direct application of the sun to the skin, except in the case of the artificial Finsen light for lupus, or more recently in the case of bone and joint tuberculosis. The author is of the opinion that insolation is not only beneficial to the tuberculous, but to the many other cases suffering from chronic pain, especially in the bones or joints, or from nervous irritability. Sunshine, when properly used, has both a powerful analgesic and a sedative action. The author hopes that if hospitals or sanatoria cannot be equipped for giving patients adequate insolation, advantage may

at least be taken of the value of carrying out this efficacious form of treatment at the home of the individual sufferer. Sunshine is a simple, cheap, and efficient analgesic sedative, of which more extensive use can be made with correspondingly gratifying results.

7. Neuroma of the Ulnar Nerve.—J. B. Ayer publishes a case of neuroma of the ulnar nerve, following an insignificant cut across the elbow, and leading to complete ulnar paralysis, with serious residual palsy. Three operations throughout a period of six years did not remove the disability. According to the author, this case teaches the importance of never allowing ourselves to be deceived by an apparently slight accident when in the region of a nerve; if progressive disability occurs, due to nerve involvement, thorough surgical investigation is indicated, with complete freeing of the nerve from scar tissue as early as possible, and precautions should be taken to prevent the formation of a similar situation. If delayed several years, regeneration may not take place.

2. Exciting of the Cardiac Reflex in Treating Enlargement of the Heart and the Aorta.—M. Solis-Cohen calls attention to the heart reflex of Abrams, which is a contraction of the heart and aorta produced by means of concussion of the spinous process of the seventh cervical vertebra. He has been exciting this reflex in many cases of dilated heart and aorta in both private and hospital practice. There were several failures, chiefly in children suffering from severe endocarditis and resulting myocarditis, with loss of compensation. In most other cases the response was marked—a lateral contraction of over an inch being usual and of over two inches being not uncommon. Before performing venesection on a patient with acute cardiac dilatation, the author concusses the seventh cervical spine, often with such success that venesection proves unnecessary.

3. Acid Intoxication in Hyperemesis of Pregnancy.—E. E. Cornwall publishes a case of hyperemesis gravidarum accompanied by an acidosis of considerable severity, in the management of which it was found possible to carry the patient through the period of intoxication without interfering with the pregnancy, thereby affording an especially favorable opportunity to observe the clinical features of this metabolic perversion, and also to test practically certain therapeutic procedures. Among the observations made on this case the following seem of special interest: The hyperemesis developed with considerable rapidity, lasted about a week and a half, and was followed by irregularly recurring nausea and vomiting, which lasted for about two weeks. No acetone nor diacetic acid were found in the urine five days before the hyperemesis appeared, but were found on the first examination made after it appeared, which was four days later; they persisted in large quantity until two days after the hyperemesis began to abate; and the acetone, not the diacetic acid, was found in the urine in gradually diminishing quantity for a week after the abatement of the hyperemesis and for one day after the urine had become alkaline. The patient craved alkalies in everything taken by mouth during the period of the acidosis. During the height of the acidosis, 20 per cent. of the total nitrogen excreted in the urine was found to be ammonia nitrogen. Half pint enemas of a 10 per cent. solution of dextrose, given every four hours, were fairly well retained, but an attempt to administer this solution by Murphy drip produced irritability of the rectum. The dextrose solution was retained better than a corresponding solution of levulose. The nausea and vomiting which persisted after the abatement of the hyperemesis, occurred more frequently in the afternoon than in the forenoon. Three months after the disappearance of the acidosis the patient appeared to be in good general condition.

4. New Growths of the Prostatic Urethra in Relation to Tuberculosis.—P. S. Pelouze, cystoscopist, Jefferson Medical College Hospital, observed during the last two years nine cases with urethral growths which presented urethroscopically almost an exact isomorphism; the symptoms bore a marked similarity, and the evidences of a coexisting tuberculosis were too constant to suggest mere coincidence. The growths were found only in the prostatic urethra, confined almost entirely to the roof and lateral walls, being most numerous just external to the vesical sphincter. They ranged from about one-twelfth to one-quarter the size of the average normal verumontanum; they were paler than the mucous membrane from which they sprang, which was usually healthy in appearance; were generally arranged in clusters, though at times isolated; were either moderately pedunculated or sessile; had none of the watery, translucent appearance of edema bullosum or the usual benign papillomata; and tiny bloodvessels could be distinctly seen passing over their perfectly smooth surfaces. From the findings in these cases and the fact that in the rather large cystoscopic service at the Jefferson Medical College Hospital the author has never encountered these masses in a patient in whom there was not very strong evidence of the existence of tuberculosis, he feels that they are in themselves sufficient warrant for a probable, if not a positive diagnosis of tuberculosis. Certainly in their presence a most careful study should be made to prove or disprove its presence.

6. Creatinine as a Test for Renal Function.—A. K. Detwiler and M. L. Griffith think that uremia is due to the failure on the part of the kidney to eliminate some products of protein decomposition or splitting which are nitrogenous; and they believe that the use of some approximately harmless normal nitrogenous constituent of the urine, as a test substance, would give a better idea of the function of the urinary tubules and also of the onset of uremia and kidney failure, than any foreign substance such as a dyestuff or drug. According to the author's experience up to now the creatinine test shows more perfectly than any other functional test, functional weakness of the kidney. Many times it is the only test which shows disturbance, and it may be that this special function is the one which is damaged especially early. This makes the test of special value in determining whether disease of the kidney exists or not, but as far as they know now it gives no basis for the classification of the lesion.

9. Treatment of Obesity.—F. A. Cummings gives the following suggestions in the treatment of obesity: Take a careful history and make a complete physical examination. Give a written diet list of what the patient may have. Be sure it is liberal and gives a variety. Do not allow fish and meat at the same meal. If the patient does not lose weight, cut down the amount of food at a meal and reduce the foods of higher starch content. Have your patients weigh

themselves regularly and report as often as necessary. Study the percentages of fats and carbohydrates as well as the caloric values of foods. Give small meals. Vary the food as much as possible.

10. Schick Test.—J. Zuckermann reports interesting observations about the Schick test and its relation to diphtheria immunity. For example, of the many cases of true clinical diphtheria occurring during the year, all had shown positive skin reactions previously. A few cases with negative reactions showed positive cultures to diphtheria. These at no time developed any clinical manifestations and were therefore considered bacilli carriers. In some cases with doubtful clinical signs, diphtheria was ruled out by the presence of a negative reaction. Thus the Schick test can to some extent replace cultures and aid materially in the diagnosis of diphtheria. The fact that it is necessary to immunize only cases giving a positive reaction has many points of advantage; the saving of antitoxin, the doing away with the labor involved in inoculating an entire ward of children, the prevention of more or less marked anaphylactic reactions, and it has replaced to some extent the isolating rooms for diphtheria. In a large institution, diphtheria is constantly making its appearance and in most asylums the problem of providing isolation, with the expense involved, is a difficult one. The author has placed diphtheria carriers among children who gave a negative skin test, and in no instance has infection resulted.

2. Cancer Mortality. — F. V. Beitler, chief of the Bureau of Vital Statistics, State Department of Health of Maryland, in reviewing the cancer mortality over a ten-year period, from 1904 to 1913, inclusive, noted a steady increase. In the year 1904 there was a mortality of 70.15 per one hundred thousand; in the year 1913 it had increased to 78.88 per one hundred thousand, a gain of 8.73 per one hundred thousand in a ten-year period. This represents an increase of 12.47 per cent. in the cancer mortality per one hundred thousand for a ten-year period. The relation of the cancer mortality to the general mortality during the same period shows a corresponding increase. In the year 1904 the deaths from cancer represented 4.24 per cent. of the total deaths, while in the year 1913, 5.60 per cent. of all deaths, an increase in its relation to the general mortality of 32.07 per cent. The cancer mortality in this ten-year period, both in its relation to the general mortality and in its relation to the population, shows a steady increase. The decline of the death rate in several of the major infectious diseases, namely, tuberculosis, pneumonia, typhoid fever, diphtheria and croup, stands in contrast to the cancer mortality.

4. Chronic Nephritis.—W. J. Barlow and R. L. Cunningham analyze 250 cases of chronic nephritis occurring over a period of twenty years in their private practice and come to the following conclusions: The prognosis of chronic interstitial nephritis is favorable when patients can be placed under proper conditions. Many cases of so-called interstitial nephritis are not true disease of the kidneys, and often these patients have no return of the abnormal urinary secretion. Patients with chronic interstitial nephritis, with good vascular and cardiac compensation, may live comfortably, and indeed, enjoy good health, for twenty-five or thirty years, and probably longer. Such patients may reach an arrest of the disease, they may be clinically well, and can be classified as apparently cured, quite as surely as in other chronic diseases.

6. Incipient Hypertrophy of the Prostate.—A. L. Wolbarst points out that the urinary symptoms associated with incipient prostatic hypertrophy are liable to be confused with functional disturbances of the bladder due to central nerve lesions, such as tabes dorsalis. Every patient with suspected prostatic hypertrophy should be carefully examined for evidence of spinal cord disease. The Wassermann test and the physical examination will often indicate that the urinary disturbances are due to central nerve disease, rather than to prostatic obstruction. The cystoscope is not to be used in the diagnosis of prostatic hypertrophy, unless the clinical data are insufficient. While the cystoscope is usually a perfectly safe instrument in the hands of the expert, it is potentially capable of doing much damage. The diagnosis of hypertrophy should be made on the clinical findings. Prostatectomy should be undertaken as a last resort, and not as a routine procedure. The bladder should be given an opportunity to compensate for the obstruction of the enlarged prostate. This can be encouraged by the application of hygienic measures tending to prevent congestion of the prostate and bladder. Massage of the bladder walls, by gently filling the bladder to its capacity, is extremely useful in stimulating compensatory hypertrophy. Prostatectomy is demanded as soon as a catheter is required to keep the patient in comfort.

7. Sodium Citrate Method of Indirect Transfusion of Blood.—I. Simons is of the opinion that we are not yet in a position to discard the direct for the indirect transfusion. In spite of the difficulties in technic attending the former, he believes it would be better to obtain the services of one skilled in arterial surgery. There is no reason to believe that hemoglobinuria may not occur with either type of transfusion with equal frequency. Having had an experience of a large number of direct transfusions, the author can say that shock is a negligible factor, that infarction occasionally occurs (lung, kidney), and that hemoglobinuria is quite common and can occur even when the tests in vitro are negative.

8. Localization of Cerebellar Tumors.—E. G. Grey points out that practically all authorities agree that nystagmus is a valuable localizing sign in diseases of the posterior cranial fossa. The author studied 51 cases of cerebellar new growths, which were localized at operation or at necropsy, to determine the proportion of patients with certified subtentorial new growths who have shown no nystagmus previous to operation. Of the thirty-four verified cases of cerebellar tumor and seventeen verified cases of extracerebellar tumor, eleven showed no nystagmus previous to operation on repeated examinations. All of the cases in which it was absent contained intracerebellar new growths. This suggests that when a patient exhibits a cerebellar tumor syndrome without nystagmus, the absence of rhythmic movements of the eyes points toward an in-

tracerebellar localization of the lesion. Among the members of both groups (that is, the group with and the one without nystagmus there were marked differences in the degree of intracranial tension. In each group there were new growths which involved the vermis and others which replaced a part or the whole of one or both hemispheres. Caloric examinations made in six of the cases in which there were no rhythmic movements of the eyes resulted in characteristic nystagmus from either labyrinth in five. Of forty verified cases of tumors lying anterior to the cerebellum, eight showed nystagmus previous to operation. Caloric examinations made in seven of the cases without nystagmus provoked characteristic rhythmic oscillations of the eyes from either labyrinth in six. These results indicate that in many cases of intracranial tumor the absence of nystagmus cannot be accounted for by an impairment of the fundamental mechanism of nystagmus.

12. Vaccine Treatment of Hodgkin's Disease.—A. R. Hatcher and W. G. Lemmon report a case of Hodgkin's disease successfully treated by autogenous vaccine and *x*-ray. They call attention to the fact that from 1832, when Hodgkin recorded a series of cases, up to 1913, the treatment of Hodgkin's disease was futile and the outcome fatal.

1. Chronic Intestinal Stasis.—W. S. Bainbridge states that the indifference with which Lane's earlier pronouncements concerning chronic intestinal stasis were received has been largely overcome. The author describes the symptoms and diagnosis of chronic intestinal stasis and in addition calls attention to a series of symptoms and diseases which Lane believes to be the outcome of chronic intestinal stasis and which have been called the end-results. Lane has enumerated a rather comprehensive list of diseases which he believes to be traceable to chronic intestinal stasis or to the lowered resistance which results therefrom, among which may be mentioned rheumatoid arthritis, tuberculosis, goitre, and cancer. It is to the last-named disease that the author wishes to direct especial attention. He is not prepared to say at the present time how far, in his opinion, chronic intestinal stasis affects the development of cancer. The whole problem of cancer is so involved that he can today merely hypothesize concerning its etiology. The interrelationship, however, of ulcers of the gastrointestinal tract and cancer of this region, of chronic irritation and cancer, and of these conditions with chronic intestinal stasis, furnishes food for serious consideration.

2. Prevention of Fistula in Ano.—P. Lockhart-Mummery points out that fistula in ano is, in the great majority of cases, an entirely preventable condition, provided that the abscess which nearly always precedes it is treated correctly in the first instance. The common mistake that is made in such cases is to temporize for a few days and to treat the case with fomentations in the hope that the abscess will subside or will become sufficiently obvious to be easily opened. The fact that this treatment gives considerable relief to the patient apparently justifies its adoption. What occurs is that in the course of a few days the abscess begins to point or bursts; there is complete cessation of pain and everybody is satisfied that the correct treatment has been adopted. The result of such treatment, however, will be almost inevitably the formation of a fistula in ano, and a subsequent operation for its relief. No harm can come from making an incision in the tissues at an early stage, even supposing that a mistake is made and no abscess is really present; the wound will rapidly heal up and cause no trouble. This is a far less serious mistake than to leave the abcess to reach a stage at which the subsequent fistula is inevitable.

4. Plumbism.—A. J. Hall states that it is curious to contrast the regularity with which we look at a patient's tongue and the rarity with which we look at his gums. And yet it is very rare to see a case of plumbism in which a careful inspection of the gums does not reveal the blue line at some part of the gum margin. One reads of the blue line being absent in persons whose teeth are kept scrupulously clean, and theoretically that is possible; but a careful search will usually find it, even in the best-kept mouths of those suffering from symptoms of plumbism. Within the last few months the author has seen three sporadic cases of plumbism which were entirely unsuspected; two were diagnosed as gall-stones and the third as alcoholic gastritis. In all three cases the blue line was present. In none of them had it been looked for. Recently some doubt has been thrown on its hematogenous origin, and it has been suggested that it may be due to lead dust in the mouth, deposited in the epithelium of the gum. If that is so, it follows that a person may have a blue line without having absorbed lead into the circulation. It is claimed that this happens in lead workers. Whether it is true or not in the case of lead workers, there is no doubt whatever that in ordinary sporadic cases of plumbism the lead-line is due to lead salts deposited in the gum from the blood, and if it is present, even though the symptoms are atypical and incomplete, no pains should be spared to find the source of the poison.

5. Tonsils and Chronic Cervical Adenitis.—H. Gardiner points out that in the majority of cases of chronic cervical adenitis where no obvious source of infection is present, the tonsils are infected. The size of the tonsil makes no difference to their infectivity, except that the small fibrotic variety is likely to be more dangerous than the large. The number of cases in which tubercle bacilli are present is relatively small, but is larger than in simple cases of enlarged tonsils. The frequent presence of other organisms than the tubercle bacillus in these cases suggests that a large proportion of the so-called chronic tuberculous glands are in reality chronic septic glands. The organisms are present in the deepest parts of the gland, and are therefore only removed by operations involving complete enucleation.

6. An Adaptable Eye Shade for Microscopic Use. S. G. Shattock.

1. Injuries of the Superior Longitudinal Sinus.—G. Holmes and P. Sargent write that experiences in the present war have made them acquainted with many conditions which are rarely seen in civil practice, and

have especially presented to them groups of uncommon neurological symptoms or clinical pictures; these are also often less complicated and more sharply defined than those due to the ordinary pathological lesions with which they were previously familiar. The vascular lesions of the brain met with in civil life, for instance, are most commonly due to arterial disease, to thrombosis, hemorrhage or embolism, while primary affections of the cerebral veins are uncommon; on the other hand, in gunshot injuries of the head, especially when tangential or superficial, disturbance of the cerebral venous circulation by depression of fragments of the skull is frequent, owing to the superficial course of the cerebral veins and the fact that their thinner walls and the lower pressure of the blood that flows through them make them more liable to be blocked by pressure than the arteries. The most striking clinical effects are, however, produced when the cranial sinuses into which these cerebral veins flow are affected, and in the authors' experience much the most common of these to be involved is the superior longitudinal sinus. They have up to the present seen over seventy cases in which the longitudinal sinus was injured or the circulation in its venous tributaries disturbed in its immediate neighborhood. In many of these cases there was no direct damage to the brain, either by the projectile or by depressed fragments of bone, but in others the disturbance of the venous circulation was associated with gross cerebral lesions. The symptoms in these cases have varied very much according to the severity of the injury and the region in which the sinus was damaged.

2. **Gunshot Wounds of the Head.**—J. E. H. Roberts states that the number of patients who arrive at the base hospitals with gunshot wounds of the scalp is large. As their injuries are apparently superficial and their symptoms few or none, there is a tendency to overlook the fact that among them there is a fairly high percentage of cases with definite injury to the skull or to the skull and brain. Any scalp wound should be viewed with grave suspicion and the necessary measures to determine the presence or absence of a fracture of the skull taken. The methods adopted by the author in treating such cases are: Careful preliminary examination. Early operation on every scalp wound, however slight. Complete excision of septic tissues at the commencement of the operation. Removal of all accessible foreign bodies from the brain. Primary suture of wounds.

4. **Treatment of Septic Wounds.**—W. A. Wood points out that he has recently treated a severely lacerated and septic wound about the knee in a child by continuous oxygenation under pressure. He had a rubber bag constructed open at both ends and provided with sleeves at the ends and with a valve through which the oxygen can be introduced. The bag was slipped over the leg like a stocking and the two ends were rendered gastight by firm bandaging or the application of a Martin's rubber bandage. Oxygen was introduced from a cylinder up to the pressure of 3 to 4 lb. which the rubber easily stands. The wound rapidly cleaned and the granulation tissue assumed a most healthy appearance in a shorter time than one would have expected. The discharge collects at the bottom of the bag and can be either drawn off by a drain tube, or the bag can easily be removed, boiled, replaced, and refilled within a short time and without pain. This method, apart from keeping the wound in an atmosphere of oxygen, keeps the wound protected and saves the patient the pain of removing and replacing the dressings. This bag, with slight additions, can also be used for continuous or intermittent saline or antiseptic irrigation; by adding a fairly large sized rubber exit tube at the bottom of the bag, connection can be made to a vessel under the bed, and when it is in position on the limb saline may be run in from a large elevated vessel, the rate of entrance and exit being regulated by nipping the tubes more or less with clips. The advantages are as follows: The wound can easily be flushed and cleansed at any time, thus removing the dead and toxic lymph and leucocytes without removing the bag. The pain of repeated dressings is obviated. The saving in dressings is enormous. There is no pressure on the limb or soiling of sheets as in the ordinary saline bath. There is no pus poultice, and the patient is comfortable in all positions; he can move the limb with bag and bath attached.

Berliner klinische Wochenschrift.

September 6, 1915.

Influence of Antityphoid Inoculation on Typhoid Cases in the German Army.—Goldschieder and Kroner begin a serial article on this subject. In the first instalment the following conclusions are reached: The duration of the fever was often abbreviated; the fastigium was absent in the inoculated twice as frequently as in the non-inoculated, and this effect varied directly with the number of inoculations which had been practised. In the inoculated, the fastigium when present was of shorter average duration than in the non-inoculated (this was due to the extreme shortness of this stage in some of the inoculated); the maximum elevation of temperature in the fastigium of the inoculated was, on the average, notably lower than in the non-inoculated; a so-called amphibolic stage was very seldom pronounced in the inoculated; a remittent course, wholly or in preponderance, was seen much more frequently in the inoculated; the fever curve in the inoculated was often seen to constitute a mild form of the typical curve, and in many cases was shortened, flattened or otherwise deformed in a manner seldom seen in the non-inoculated.

A New Form of Wound Treatment.—Salomon has devised an application for wounds which consists of some form of petrolatum of low melting point to the extent of 97 per cent., the remainder consisting of a solution of crude rubber in ether or toluol. This ointment may also serve as a vehicle or base for resorcin, extract of hamamelis or other drug. The base itself is a wax-like substance which liquefies at 40° C. In order to apply it, it should first be heated to 90° C. in a water bath. It causes a marked hyperemia and is of striking benefit in tenosynovitis, arthritis, inflamed varicose veins, furuncles and carbuncles. In the latter the cores soon showed liquefaction and were readily impressed. The melted ointment was brushed directly upon and around wounds and cotton laid over all. A coating was then applied over the cotton. After cooling the cotton was stripped off along with the ointment. In this manner, all impurities were removed from the wound and a more permanent dressing applied. This was renewed daily. Offensive odors sometimes noticed had no bearing on the course of healing. When the latter had advanced to a certain degree, milder ointment or powders were substituted. The remedy was applied directly to suppurating surfaces, as large shell wounds, and served well for cleansing them. The author, however, speaks of applying sublimate solutions as well, and this alternation of water with greasy substances made it necessary to remove the latter from the surrounding skin with benzine. The principal motive of the author in devising this application seems to have been to secure economy in dressings, together with its natural simplicity. It is also especially valuable for

large defects made by shell fragments which heal, the author says, in a surprisingly short time, when treated in the manner described.

Münchener medizinische Wochenschrift.

September 7, 1915.

Treatment of Diphtheria.—Seidel claims to have made some novel observations on this subject. Diphtheria is a simple affection. Certain microorganisms begin to flourish in the tonsils and secrete a poisonous substance which enters the blood, in which it remains but a short time, its fate being to traverse the walls of the vessels and anchor itself in the tissues. An antiserum to be of certain worth must be thrown into the blood while the toxin still circulates within it. The toxin and antitoxin unite very slowly, not instantly, as was once believed. Hence when given early enough intramuscular injections are indicated, although one good intravenous injection should be associated with the first one. In the adolescent and adult it may be repeated, but in the young child the practicability of such a course is questionable. In making an early intravenous injection the author is not guided by the membrane but the general symptoms. In a material of 32 cases, all those injected before the third day lived. All fatal cases had not been injected until after the third day. In establishing the diagnosis the author finds that tonsillar smears are frequently sterile as far as the Klebs-Loeffler baccillus is concerned, while in not more than 20 or 30 per cent. do culture attempts succeed. To inject a negative case with antitoxin means to invite a possible anaphylaxis on repetition of the step but anaphylaxis cannot develop in the first six days, and the real danger lies in reinjection after intervals of weeks or months. In other words to inject without sure indication might handicap the child should it develop the actual disease within a year. But the danger of death is infinitesimal—perhaps one fatal case of anaphylaxis in 200,000 injections. The author's experience has been that the early combined method of injection prevents complications and that tracheotomy is never required.

Salt as a Preventive of Sweating in Consumptives, Soldiers on the March, etc.—Link proceeded in a research with the datum that the night sweats of the consumptive rob him of much salt. A man under excessive sweating can lose nearly half an ounce of NaCl, and if a consumptive is given a teaspoonful or so of the latter in half a glass of water upon retiring he will fail to perspire as usual. The mechanism of the phenomenon is not clear but the salt must confer some property upon the blood in virtue of which it does not readily part with its water. The author then tested this property of salt in healthy subjects—troops on the march in the hot sun. These men normally sweat, become thirsty, drink and sweat again—a vicious circle. There was a possibility also that loss of salt in this manner might be responsible in part for sunstroke. One hundred soldiers received each an even teaspoonful of salt before a march. The men were to march about 30 kilometers in sultry weather, and they sweat much less than their fellows and also drank much less water. Other tests, however, did not result in these differences, so that only under special weather conditions when men sweat profusely is a difference in marked evidence. Several years ago sodium bicarbonate was recommended as a preventive for sunstroke upon the theory that it maintained the isotonic quality of the blood. But this salt, the author says, has the disadvantage of neutralizing the gastric juice and very often of deranging the gastric functions while sodium chloride is entirely free from this drawback.

Deutsche medizinische Wochenschrift.

September 9, 1915.

Meningococcus Sepsis.—Professor Bittorf has seen recently four cases of this sort, the clinical picture having been uniform. An angina was accompanied, or followed, by a chill or fever or both, which ushered in a complete picture of general sepsis. On the first or second day a typical septic-embolic examination appeared most pronounced distally on the extremities. The lesions were extremely small, livid, round or elongated, invested by an areola itself not larger than a lentil, of a hyperemic-hemorrhagic character. New crops continued to appear and there was perceptible a slight induration at the center, which coincided with a minute focus of suppuration. Vesiculation and umbilication were at times in evidence. Crusting and cicatrization were seen in some lesions. There were also efflorescences which did not extend beyond the roseola stage. Herpes labialis was present in every case; once there was an intercostal zoster seen and once herpes of the cornea. In general there was an initial tendency to joint manifestations—pain and swelling. Individual cases showed individual phenomena which need not be detailed. All complained of a general prostration and headache. Meningitis appeared only as a late symptom, and lumbar puncture then made the diagnosis. The meningococcus was not found to a marked degree until after repeated examinations. Three patients recovered, the fourth dying of paralysis of the respiratory center. The diagnosis of a primary sepsis was evident from the exanthem, the initial joint disturbances, splenic tumor (absent, however, in one case), and character of the fever. The meningococcus doubtless caused an initial angina — in three cases tonsillitis, in the fourth swollen lymph nodes at angle of jaw—and proceeded at once to infect the blood. The meningitis was a blood metastasis. In regard to treatment and whether it affected the outcome it can only be said that the spine was tapped several times and that salicylic acid and urotropin were pushed. Serum was not used. Cases of this type have occasionally been reported, although perhaps not interpreted like the present ones.

Glycerophosphate vs. Sulphate of Magnesium in Subcutaneous Narcosis.—Professor Kobert inspired one of his students, Krause, to write his inaugural dissertation on this subject. The sulphate has undoubted narcotic powers in tetanus but lowers the blood pressure. A complete case had been made out in connection with the glycerophosphate and a well known drug house had placed a glycerophosphate on the market, when Zuelzer got in print with the announcement that this salt given in 25 per cent. solution 10 c.cm. eight to ten times daily was of service in tetanus. But while the author and Krause worked with animals only and were not convinced that magnesium controlled the nerve centers, Zuelzer tested the glycerophosphate on mankind and apparently with satisfactory results, *i.e.* it maintains the narcotic action of the magnesium. The author, however, had a large mortality among his animals, even in the absence of blood pressure lowering, and was forced to conclude that the glycerophosphate was more dangerous than the sulphate for man. He is pleased to find that his misgivings in this respect may have been causeless.

Age of Parents a Sex-Determining Factor. — R. J Ewart in a study of the influence of the age of the parents on the number and the sex of the offspring, both in the first and second generations, infers from the evidence collected that more males are born, the older the grandparents were at the time of the birth of the parents.—*Journal of Hygiene.*

Insurance Medicine.

The Role of Traumatism in Disease Calling for Compensation.—Sir Thomas Oliver, M.D., F.R.C.P., Professor of the Principles and Practice of Medicine, University of Durham College of Medicine, Newcastle-on-Tyne, England, in a paper read before the Assurance Medical Society of London, on May 5, 1915, showed that in the evolution of industrial legislation employers have been forced to accept responsibility for all accidents to their workmen occurring in service. By the Employers' Liability Act, liability was possible only if there had been negligence on the part of the employer, but by the Workmen's Compensation Act negligence as a contributory qualification is no longer necessary, on the part of either the employer or the workman. As legislation proceeded it became difficult to separate accident from industrial disease. Upon suddenness of development and unexpectedness County Court judges descanted, laying stress upon these phenomena as the distinction between accident and disease, but a fatal attack of anthrax in a workman who had opened a bale of infected wool demonstrated the unreliable foundation upon which this distinction rested. The malady in this case was both a disease and an accident.

More interesting, however, are the cases where, given the history of an accident, the injured person dies through the development of disease, and the dependants claim damages on the ground of the disease having been the outcome of the injury received. In view of the liability of employers for accidents under the Workmen's Compensation Act, the subject of traumatism and tuberculosis is not only interesting but important, and one on which medical men should have, as far as possible, a definite opinion. Sir Oliver cites the following case: Eighteen months ago a mason's laborer who had never lost time through illness fell from a scaffolding a distance of six feet, injuring his right hip and chest against a brick wall. At the close of the day's work the man walked to an adjoining railway station and took the train home. Nine days later he had his first hemoptysis. He recovered from this and returned to work. Six weeks after the accident he complained of pain in the right chest. On examination signs of pleurisy were found. The patient gradually became worse and emaciated rapidly. Cough increased in frequency and severity, expectoration containing tubercle bacilli. There was evidence of disease at the apex of the right lung. The case went into Court, and the judge awarded full compensation to the claimant on the ground that the pulmonary disease was the result of the accident. This shows the relation of chest injury to subsequent development of pulmonary tuberculosis, in which there would appear to be a distinct relationship between the two.

But a sequence of tuberculosis is also observed in injuries to the joints and bones. In the great majority of joint cases, however, the injury at the time of occurrence is of such a slight nature that it fails to attract the attention of the patient, while in the cases of injury to the chest wall with subsequent tuberculosis the injury has been of a serious nature. Hemoptysis has been one of the earliest signs of internal injury, occurring one or two hours after the accident or not until several days later. The result was the same, pulmonary tuberculosis.

Is there such a malady as that of which the textbooks speak, viz., *phthisis ab hæmoptoë?* Experimental investigation throws light upon the subject. Animals have had the trachea opened and healthy blood injected into the bronchial tubes. When kept in a warm atmosphere they recover without any bad effects, but if allowed to run about in the open air, exposed to cold, a low grade of inflammation in the lungs has been discovered. From this it would appear as if the presence of blood in the pulmonary alveoli and the bronchial tubes could induce pulmonary disease, the terminal stage of which by infection becomes tuberculous. The blood in the alveoli acts as an irritant, the local resistance of the lungs is lowered, and the lung tissue becomes a prey to all kinds of microorganisms, including tubercle bacilli. What is the cause of the hemoptysis which follows an injury? The delay in its development and the manner in which it recurs suggest the presence of preexisting disease, and, as a result of the contusion lung tissue which had undergone some change of structure had become more friable and therefore more easily torn.

Can we speak of such a disease as traumatic pulmonary tuberculosis? Where localized tuberculosis has declared itself after an injury, inquiry ought to be made into the previous health of the patient, always bearing in mind the fact that in about seventy per cent. of post-mortem examinations made in infirmaries upon the bodies of persons not having died from tuberculosis, there are evidences in the lungs of healed or latent tuberculosis so that if an injury to the chest wall had happened to any of these persons, the lung tissue at the site of a pulmonary focus might have been injured, tubercle bacilli have been liberated in conditions favorable to their growth, with the resultant established pulmonary disease. It is interesting to remember that when death has followed injury to the chest wall the lung opposite to the side injured has sometimes shown more serious lesions than the lung on the injured side.

Diabetes insipidus is known to follow some cases of head injury. Sir Oliver cites a case of his in which a healthy man fell from a scaffolding on a ship and hit the back of his head. He was rendered unconscious for several days. On recovering consciousness his first request was for water. Thereafter polyuria and polydipsia were established and persisted. Changes occurred in the optic disc proceeding to atrophy. This case was one of diabetes insipidus as the result of injury and it was one for compensation.

Locomotive engineers as a class die from diabetes mellitus in larger numbers than men engaged in most other occupations. The prolonged strain upon the nervous system created during long distance running may be responsible for the malady. Admitting this, the type of life, the heredity and other influences cannot be ignored altogether in decision for compensation. Apart from these, if it can be demonstrated that persons employed in any particular occupation die from a disease in larger numbers than persons engaged in other trades, some occupational influence must be at work over and above those alluded to.

With reference to cancer and traumatism, experiments on animals have proved that inoculation with cancer growths produced no results, but when the previous healthy tissue was injured and then inoculation occurred, cancer was produced. The local injuries produced as important a part in causing the disease as the inoculation itself.

Book Reviews.

DISEASES OF THE DIGESTIVE ORGANS. With Special Reference to Their Diagnosis and Treatment. By CHARLES D. AARON, Sc.D., M.D.; Professor of Gastroenterology in the Detroit College of Medicine and Surgery; Consulting Gastroenterologist to Harper Hospital. Illustrated with 154 Engravings, 48 Roentgenograms, and 8 Colored Plates. Price, $6.00. Philadelphia and New York: Lea & Febiger, 1915.

THIS is a volume of 790 pages and comprises 51 chapters, of which the first 13, including 231 pages, are devoted to the subjects of the physiology of digestion, the examination of the stomach contents and of the feces, Roentgen-ray examination, diet in gastric and intestinal diseases, artificial food preparations, lavage of the stomach, massage and electricity, treatment of diseases of the intestine through the rectum, hydrotherapeutics and mineral waters, and medications in gastric and intestinal diseases. The following chapters start with diseases of the mouth and take up in succession the pharynx, esophagus, stomach, liver, gall bladder, bile ducts, pancreas, small intestine, vermiform appendix, cecum, colon, sigmoid flexure, rectum, and anus. Considerable attention is paid to the subjects of diagnosis and treatment. All the latest methods of examination are given in detail. Thus, the various tests and reactions for the diagnosis of carcinoma of the stomach are fully described, including the Wolff-Junghans, Abderhalden, Gluzinski, Salmon, tryptophan, hemolytic, antitryptic, meiostagmin and cystodiagnostic tests. The methods of *x*-ray examination are fully presented and the Roentgenograms accompanying this section of the work are particularly helpful. These and the numerous other illustrations are of a high order of artistic merit. On the whole, one may characterize this work as an eminently practical treatise which covers the ground fully in an interesting manner. It is well written and may be used both as a textbook and as a work of reference.

KLINISCHE BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG (mit Ausschluss der Tuberkulose). Herausgegeben von Professor Dr. L. BRAUER, arztlichem Director des Allgemeinen Krankenhauses Hamburg-Eppendorf. Redaktion, für die Originale: Professor Dr. H. SCHOTTMÜLLER (klinischer und bakteriologischer Teil) und Professor Dr. H. MUCH (immunitätswissenschaftlicher Teil), beide am Allgemeinen Krankenhaus Hamburg-Eppendorf. Für die Ergebnisse: Professor Dr. H. LUDKE, im Würzburg. Vol. III, No. 3. Vol. IV., No. 1. Price per volume, 20 marks. Würzburg: Curt Kabitzsch, 1914.

THE two numbers here presented contain important contributions and reviews in the domain of the infectious diseases and immunology, some of which have already been referred to in the editorial columns of the MEDICAL RECORD. The first of these numbers contains the following articles: The Influence of Immunological Research upon the Study of Specificity, Digestion and Assimilation, by Hamburger; Hemorrhages in Scarlet Fever, by Klimenko; The Partial Antigens of the Staphylococci, by Strubell-Böhme, and reviews by Kleinschmidt on The Natural and Artificial Formation of Diphtheria Antitoxin in Man; and by Luckenbein on Treatment with Tumor Extracts and its Results. The second number contains the following articles: Etiological Researches on Typhus in Serbia in 1913 and Hamburg in 1914, by von Prowazek; A Case of Purpura with an Eruption of Hemorrhagic Vesicles, by Lindvall; Abscess of the Lung, by Josefson and Bladini; and Clinical Manifestations Following Prophylactic Typhus Inoculation, by Romer. The reviews are by Jochmann on Septic Endocarditis and by Schmitt on The Specific Treatment of Gonorrhea.

THE CLINICAL ANATOMY OF THE GASTRO-INTESTINAL TRACT. By T. WINGATE TODD, M.B., Ch.B., Fr.R.C.S., Eng., Henry Willson Payne Professor of Anatomy in the Western Reserve University, Cleveland, Ohio; late Lecturer in Anatomy University of Manchester. Price, $1.75 net. London, New York and Bombay: Longmans, Greene & Co., 1915.

IN the volume before us Mr. Todd has embodied the substance of the course of lectures on the alimentary canal as given in the Anatomical Laboratory of Western Reserve University. The alimentary canal is discussed from the clinical standpoint, but the mouth, pharynx, tongue and salivary glands have not been considered owing to the fact that only results of recent investigation which are of value for clinical purposes have been included. Also clinical research on the mouth and pharynx has not progressed so rapidly as has investigation on the abdominal part of the alimentary canal. Elementary facts have been omitted and the book is an outline of advanced anatomical knowledge regarding the alimentary tract. The work should prove useful to students and practitioners.

FEWER AND BETTER BABIES or The Limitation of Offspring by the Prevention of Conception. The Enormous Benefits of the Practice to the Individual, Society and the Race Pointed Out and all Objections Answered. By WILLIAM J. ROBINSON, M.D., Chief of the Department of Genito-Urinary Diseases and Dermatology, Bronx Hospital and Dispensary; Fellow of the American Medical Association and of the New York Academy of Medicine; Member of the American Urological Association, American Medical Editors' Association, etc.; Editor of the *Critic and Guide* and of the *American Journal of Urology, Venereal, and Sexual Diseases*. With an Introduction by A. JACOBI, M.D., LL.D., Ex-President of the American Medical Association. Price, $1.00. New York: The Critic and Guide Co., 1915.

THE title-page indicates the purport and tone of this book. The author believes "that under any conditions and particularly under our present economic conditions, human beings should be able to control the number of their offspring.....the knowledge of preventing undesirable conception should not be considered criminal knowledge.....and its dissemination should be as permissible and as respectable as is the dissemination of any hygienic, sanitary, or eugenic knowledge." The supposed physiological, hygienic, economic, and moral objections to the prevention of conception are discussed in detail and attempts are made to answer them. The subject is one that requires careful philosophical analysis and perhaps false impressions may be created by rhetorical phrases which merely tend to cover what some more careful readers may regard as poor logic. The author has, however, written an interesting brief that cannot fail to stimulate thought.

CHIRURGISCHE OPERATIONSLEHRE FÜR STUDIERENDE UND AERZTE von Prof. Dr. FRIEDRICH PELS LEUSDEN ord. Prof. der Chirurgie und Direktor der chirurgischen Universitätsklinik und Poliklinik zu Greifswald. Zweite, wesentlich verbesserte Auflage mit 766 Abbildungen. Berlin und Vienna: Urban und Schwarzenberg, 1915.

THE first edition of this work appeared in 1910 and the present one is enlarged to the extent of sixty pages only; even this accession could be accounted for by the addition of a hundred illustrations. The author states in his second preface that his principal efforts have been in the direction of increasing the quality rather than the quantity. Slight gaps have been filled, defects have been made good and errors corrected. The one addition mentioned by him is in the domain of local anesthesia. Although the war was well under way when this preface was written the author states that his patriotism is not involved in a scientific effort like the present. If there is more German surgery than foreign surgery, it is because he knows more about the former and its literature is more accessible; but he has endeavored to do justice to the work of colleagues in other countries. The number of illustrations is practically equal to the number of pages which virtually makes the work an atlas, allowing for the omission of colored plates. The surgical advances of the past five years are represented largely by the additional illustrations. Two omissions worth noting are a list of illustrations and a register of proper names. These might have indicated almost at a glance the real amount of progress represented.

THE INSANITY OF YOUTH AND OTHER ESSAYS. By BAYARD HOLMES, B.S., M.D., author of "The Friends of the Insane." Price, $1.00. Cincinnati: Lancet Clinic Publishing Company, 1915.

THE essays on the insanity of youth and other subjects are reprints of articles written for the most part as editorials for the *Lancet-Clinic* by Dr. Holmes. They are interesting and to a considerable extent instructive and should serve to attain the author's object, that of arousing attention to various conditions relating to the insane.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-fifth Annual Meeting Held at Philadelphia, Sept. 20-25, 1915.

SECTION ON SURGERY.

Tuesday, September 21—First Day.

Treatment of Fractures a Lost Art.—Dr. JOHN B. ROBERTS of Philadelphia read this paper, saying that the bone wounds had been neglected in recent years. Adherence to the ancient idea that loss of rigidity and displacement of fragments alone needed treatment was a common error. Some closed fractures must be incised and "fixed" directly. Some were treated well either by operative attack or a non-blood-shedding method. Others should not be operated upon even by the most sanguinary surgeons. Vivisection and carpentry were not the sole method of obtaining good union and good function. Mechanical instinct, anatomical knowledge and surgical common sense were the keys to success. The esentials of subcutaneous fracture treatment so far as the injury was concerned were anesthesia, with comparison of the normal limb and accurate reconstruction of bony contours; verification of the line of fracture and accuracy of reduction by *x*-rays when practicable; anatomical and physiological knowledge of muscles and bones; well fitting retentive appliances; early frictions, skillful early mobilization and careful massage with frequent inspection.

The Treatment of Complicated Fractures and Present Opinion of Operative Treatment.—Dr. JOHN B. LOWMAN of Johnstown read this paper stating that the open treatment of fractures had taught us that in some cases delayed union was caused by too close approximation, thus inhibiting callus-formation, producing bone absorption and leading to infection and necrosis of bone; it had also taught us never to plate a compound fracture. The open treatment was indicated in fractures which could not be properly reduced, especially complicated fractures around joints. Bone-grafting seemed to be superior to all other methods, although these other methods had their advantages. In all fractures of the bone shaft plating was the best method and should be done as early as possible. Out of twenty-five cases of fractures of the shaft of the femur plated, 23 of the men were back at work at their former occupation; this had been the exception in those treated by the closed method. Bone transplants from one species to another did not grow; those from one person to another grew in 40 or 50 per cent. of cases, while those which were autogenous grew with very trifling exception. The success of open treatment depended upon the mastery of the very careful technique which bone surgery required.

Dr. WILLIAM L. ESTES of South Bethlehem said that the American Surgical Association had appointed a committee two years ago to standardize as far as practicable the various results as regards treatment of fractures, but at the very outset their work had been almost entirely nullified by the sad fact that they could get proper records from only a very few sources in the United States, and for that reason the committee had elaborated a form of record which they were trying to have introduced and which they believed would give them an opportunity to collect data which would finally lead to some sort of result in establishing what ought to be the proper treatment of the ordinary fracture.

Dr. P. G. SKILLERN, Jr., of Philadelphia said that nitrous oxid gas should always be administered to afford the surgeon as well as the patient the best conditions for a complete reduction. After the attempt at reduction a skiagram should be taken. If the fragments were still unreduced, the cycle of administering gas, reducing, and taking a skiagram should be repeated. It might be necessary to repeat this cycle two, four, or even six times in obstinate cases, but each cycle was harmless, though perhaps slightly inconveniencing to the patient. It was only after such repeated attempts by their failure proved the fracture to be irreducible clinically that operative treatment was indicated. After reduction a copiously padded and carefully applied fixation dressing should be put on, treating each fracture in an individual, and not a routine manner. Of the methods of operative fixation, that by the use of metal plates was the least desiroble, and, if indicated at all, metal fixation was best employed for fresh fractures and not—and Mr. Lane himself had emphasized this—for cases of non-union. For non-union by far the best method was the employment of the autogenous bone-graft.

Dr. EDWARD MARTIN of Philadelphia made an appeal to the assembled surgeons to aid in the work of the Fracture Committee of the American Surgical Association by each in his own institution insisting upon the keeping of adequate records both graphic, mensural and verbal, of his cases of fracture. The treatment they received, the complications which might have developed and the immediate and remote functional and anatomical result. Thus quickly would be available a mass of accurate information upon which might rationally be based a formulation of the successful treatment of fractures. He was in accord with the dictum that metal plates always delayed union and were to be avoided save in exceptional cases. The statistics studied by Estes showed that operative treatment was less frequently required in children than in adults. This in part is due to the fact that in the young a moderate deformity had a tendency on use to gradual correction. Such tendency was never exhibited in the adult. In the latter a good union with moderate and allowable deformity, if the bone were a weight-bearing one, might become on use a crippling and deforming one. Hence, given even a slight angulation of the leg bone, weight-bearing should not be allowed for many months. And, moreover, for his own protection it was of vital importance that the surgen should have written measures and *x*-ray records of the case on discharge and evidence that advice against weight bearing had been given.

Dr. CARLES E. THOMSON of Scranton said that it had always seemed to him that the atmosphere of mystery surrounding fractures was being cleared up very rapidly to-day when we were all working on the subject. Mr. Martin alluded to the often delusive or defective Buck's extension. He would say the always delusive or defective Buck's extension and say it because the objection to it was that it did not extend. In regard to Dr. Estes' statement that fractures should be treated by skilled surgeons, that was not practicable. Fractures were occurring in the country and the skilled surgeons were expected to live in the big medical centers. The general practitioner had to treat them and they would continue to have to treat them. Dr. Roberts said, "Teach your students to treat fractures." That was the key to the situation.

Acute Pancreatitis.—Dr. JOHN B. DEAVER of Philadelphia read this paper saying that by acute pancreatitis we ordinarily understood the classical severe type described by Fitz in which there was hemorrhage and extravasation of pancreatic juice resulting in profound general shock, intoxication, and local destruction of tissues with ensuing gangrene or suppuration. In the last few years surgery had revealed that the lesser inflammatory lesions of the pancreas were common. It had not been sufficiently pointed out that acute pancreatitis without the severer manifestations of hemorrhage and ferments was not uncommon. Many cases had been operated upon, unrecognized and attributed to disease of the biliary tract. The treatment of pancreatitis had not as yet been standardized, because of lack of knowledge of its exact cause and the mechanism of its production. Pancreatitis was a result of infection or duct obstruction or a combination of the two. Operative intervention should aim to establish the cause and relieve it. Infective pancreatitis secondary to disease of the biliary tract should be treated by the measures adapted to relief of biliary infection. Obstructive pancreatitis due to stone in the papilla of Vater or to other abnormality of the papilla demanded relief of the obstruction. In ultra-acute cases the question of operability entered strongly and might forbid everything of acute abdominal cases to the medical wards of the hospital. By the time they reached the surgeon in this roundabout way much valuable time had been lost.

Dr. ERNEST LAPLACE of Philadelphia said that there had always been some mystery connected with the question of disease of the pancreas. This question of pancreatitis was in the same condition as appendicitis had been fifteen or twenty years ago. There was no such thing as a pancreatitis alone any more than an appendicitis alone. When a violent pain takes place in the epigastrium with symptoms of shock, immediately that patient should be transferred to the surgeon and we would be able to drain at once. Some of these cases were accompanied by a dilated duodenum with intestinal sepsis as a predisposing cause to the infec-

tions which traveled up through the ampulla of Vater and gave to the pancreas whatever infection had found its way up there. In regard to the complications of pancreatitis and cholecystitis they traveled together. It was the same infection. Dr. Deaver had rendered the profession a very great service when he called attention to the lymphatics. The duodenum and pancreas were supplied by the same lymphatics and the spleen and body of the pancreas by the same lymphatics. He made a plea for early operation.

Dr. Lawrence Litchfield of Pittsburgh said that he had been associated with medical wards for the past twenty-five years and had often regretted the time lost by the fact that these cases were first sent to the medical wards. He wished to emphasize also the fact that valuable time was lost in many cases by delaying operation too long in the hope of making a definite positive diagnosis. There were several conditions in which an operation must be undertaken before a positive diagnosis could be made if the patient's life was to be saved.

Management of Toxic Goiter.—Dr. Charles H. Frazier of Philadelphia read this paper, stating that toxic goiter might be either that which began as simple goiter and became transformed into the toxic variety or the true exophthalmic goiter. The principal distinction to be made surgically was in reference to the severity of the case. The treatment of this condition belonged essentially to the domain of surgery. If the circumstances of a person suffering with moderate thyrotoxicosis were such as to render impracticable a prolonged period of rest, he strongly urged immediate operation and proceeded to the removal of as much of the offending gland as conditions indicated. The mortality was insignificant; personally he had not lost a case of the type. In a grave form of intoxication the watchword was caution. It was out of the question to say what the order of procedure should be until after the patient had been under observation in bed for a few days during which a study of the body functions and all the available secretions and fluids had been made. Each case presented its own problem as to whether it should be treated by boiling water injections, ligation of one or more vessels at once or more sittings or by partial thyroidectomy. A good working rule when in doubt was to err on the side of conservatism. A patient should not be operated upon in the stage of acute exacerbation. Rest was the most fruitful non-operative measure. He had tried the *x*-rays and radium without appreciable effect. In all operative cases anoci-association was employed routinely and successfully. Nitrous oxid anesthesia was always used. The relation of the thyroid to other ductless glands, especially the thymus, should not be overlooked. In 76 thyroidectomies for toxic goiter he had no death and in twenty-four ligations two deaths. He would not at this time consider such cases as the two fatal ones suitable for that particular operation at that cycle of the disease.

Dr. John de V. Singley of Pittsburgh said that so many interesting points had been taken up that it would only be possible to refer to what Dr. Frazier had very wisely emphasized as to the necessity for discriminating between the acute exacerbations of toxic goiter and the terminal stages of the disease with impending death. Careful interpretation of the history and of the clinical manifestations of toxic goiter had taught us to avoid operation during the periods of exacerbations, and in the final stages of the disease. To this, much more than to any great improvement in operative technique, was due to the marked reduction in operative mortality that had taken place in recent years. The earlier goiter patients were operated upon, after the onset of toxic symptoms, provided operation was not done during acute exacerbations, the better the results, both immediate and remote. No operation was of any avail and any would probably prove fatal in the most serious advanced cases, with widespread terminal degenerations, especially of the heart muscle, with irregular pulse, low blood pressure, and periodical attacks of delirium cordis (Kocher). The after-treatment was of the greatest importance. These patients should not be discharged from the hospital after operation to work out their own salvation as they too often were. Careful supervision by a competent medical advisor should be carried out for several years at least.

Dr. James D. Heard of Pittsburgh said that the severity of the cardio-vascular disturbances in toxic goiter made it important that patients of this type should be carefully studied in regard to disturbances of cardiac mechanism before submitting them to operation. Alternation in force of ventricular systole should be diligently sought for, and when found in connection with a heart rate which was approximately normal, it was to be regarded as greatly increasing the gravity of prognosis in a given case. The administration of belladonna should not be routine. It should be remembered that belladonna in full dosage removed the inhibiting action of the vagus and that this result would be undesirable in cases where the heart rate was already unduly accelerated. For like reason, the administration of tropin to guard morphine would be unscientific. Morphine required no guarding. It acted favorably in these cases, partly through its action on the vagus and it would be a distinct disadvantage to remove this inhibitory action in cases where the heart rate was already accelerated.

Dr. G. M. Astley of Philadelphia said that Dr. Frazier had said that between partial resection or ligation choose ligation, or if boiling water and ligation choose the boiling water. From what he had seen it was a question in his mind as to whether injections of boiling water should not be used first. The problem seemed to be the throwing out of commission of a certain amount of gland substance. That was done by ligation or boiling water. The boiling water would promptly throw out of commission that substance. He had known that where boiling water had been used the subsequent surgical sections were very simple.

Dr. S. J. Waterworth of Clearfield stated that if we avoided the trachea he believed we would have fewer symptoms following operation. As to operation following hot water injections, he had injected it with hot water and knew it rendered operation much more difficult. There was produced a general thyroiditis. The tissues became matted together and there was more difficulty in getting the goiter out. He thought there was a great distinction to be made between the cases coming into the office with the first flush of hyperthyroidism and those which are older. Upon the discrimination of the surgeon will rest his mortality rate.

Dr. Frazier, in closing, said that he was not prepared to speak very enthusiastically about boiling water, as he had used it in only three cases. He had been interested in regard to what Dr. Heard said in reference to careful studies of heart action before operation was performed. Certainly surgeons should avail themselves of opportunities to have experts and consultants come in and study these cases whenever possible. The suggestions Dr. Heard made in regard to tracings and belladonna he was very grateful for.

Rectal Anesthesia in Thyroidectomy.—Dr. Walter Lathrop of Hazleton read this paper, saying that in the oil-ether rectal anesthesia the brain was not deeply narcotized and the patient regained consciousness rapidly, while the sensation of pain was held in abeyance for a considerable time. The eye reflex was seldom lost, but muscular relaxation was complete. The method was very valuable where fear was a prominent element as was the case in hyperthyroidism. The postoperative effects were much milder than after inhalation narcosis. In thyroidectomy, where freedom from obstruction in the operative region was desirable, the rectal method was ideal. Also the patient could be anesthetized in bed and removed to the operating room and thus have no conception of what had occurred. This was a great aid in realization of the anoci-association method. He had used the method in 118 cases since June, 1914, with most satisfactory results.

Dr. John W. Luther of Palmerton stated that his experience with colon-oil-ether anesthesia was limited to 47 cases. However, his experience differed from Dr. Lathrop's in that 36 had been abdominal operations, where complete muscular relaxation was of greater importance than in head and neck work. In 22 of his cases no additional anesthesia had been required and in 18 of the remaining cases only a dram to an ounce of ether by inhalation had been needed. The duration of operation varied from 15 minutes to 2 hours. On account of the slowness in preparation the method was not suitable when several cases were to be operated upon in succession. One of his cases died of pneumonia 7 days after operation, but this had been a septic case and the result could not be attributed to ether. The narcosis was uniform from start to finish.

Dr. W. Hersey Thomas of Philadelphia said that his experience in operating upon 73 patients under colonic anesthesia had convinced him of its value in selected cases. He had not found that rapid return to consciousness was the rule. Although the presence of some of the superficial reflexes would indicate a light

anesthesia, the great majority of his patients had been profoundly anesthetized. He had seen the anesthesia deepen after return of the patient to the ward in spite of rectal irrigation. The conviction had grown that the liver, which bore the brunt of the attack in this method, was markedly affected and that it was a toxic change in this viscus that prolonged the anesthesia. The return of consciousness was hastened by the introduction of saline solution. The patient should be kept under skilled observation for several hours after return to the ward.

Dr. LATHROP, closing, said that in abdominal cases he had had quite an experience, especially in miners having asthmatic conditions. If you started ether in these cases they choked right up and you had to stop. These cases slept perfectly under rectal aesthesia. So far as arousing them was concerned, he had seen very few who could not be aroused.

Wednesday, September 22—Second Day.

Surgical Treatment of Ascites.—Dr. ROBERT T. MILLER, JR., of Pittsburgh read this paper, in which he said that it dealt only with that group of cases in which ascites was associated with cirrhosis of liver Five cases of ascites were considered, 4 of which were due to alcoholic or luetic cirrhosis of the liver and the fifth almost certainly due to malignant diseases. The patients varied in age from 18 to 60 years. Ruotte's operation was done in each case, 4 times unilaterally and once bilaterally (two sittings); in 3 cases general anesthesia was used and in two local anesthesia. There was no mortality except in the malignant case whose death was apparently in no way due to operation. In all but the malignant case, abdominal paracentesis had been necessary at frequent intervals before operation; after operation, the necessity for tapping the abdomen had been absolutely done away with in 2 cases and all but eliminated in 2 other cases, while in the fifth case (malignant) the abdomen had not been tapped either before or after operation. In 1 case operation (double) had been followed by a decrease of the umbilical circumference from 110 cm. to 97 cm. and an increase in average daily urinary output from 480 cc. to 1250 cc. Of the 4 cases of cirrhosis of the liver, 3 were restored to self-support and the fourth, a boy of 18, was advanced from a condition of invalidism to a position of helpfulness in the household. In no instance had any ill effect been observed from drainage of the ascitic fluid directly into the circulation. Five cases were too few from which to generalize, but the writer felt that the results obtained in this series were encouraging; so good, in fact, as to warrant him in warmly recommending a trial of this method.

Dr. JAMES D. HEARD of Pittsburgh said that it was probable that surgical procedures would soon largely supplant the so-called medical treatment of ascites due to cirrhosis of the liver. Statistics available as to the result of the Talma operation showed that 35 per cent to 50 per cent of cases of ascites due to cirrhosis of the liver might be cured as the result of early operation. These statistics should be brought prominently to the notice of internists. The statistics of Ruotte, Soyesima and Miller indicated that venoperitonostomy was capable of yielding such favorable results that a further trial of this method was to be strongly recommended. Operative measures should be resorted to in early stages of ascites before the patient had been subjected to the local irritation which resulted from frequent tappings, repeated withdrawal causing loss of proteid, and general failure of patient owing to the continuous presence of a condition which, in spite of repeated tappings, usually slowly progressed toward an unfavorable end.

Dr. J. E. SWEET of Philadelphia said that in 1876 a Russian army surgeon, von Eck, had devised his operation called the Eck fistula, that is, anastomosis between the portal vein and the vena cava. This operation had been applied only three or four times. Usually in true cirrhosis the portal vein was so tied up in adhesions that a true Eck fistula was not feasible. Dr. Edward Martin and Dr. Sweet had devised a modification of the Eck fistula, consisting of an anastomosis of one of the large mesentric veins with the iliac vein at the point where they crossed. He felt that some modification of the Eck fistula such as he had referred to would be a more positively curative procedure than would this operation developed by Dr. Miller, which amounted to continuous tapping.

Fulguration Treatment of Bladder Papilloma.—Drs. A. A. UHLE and W. H. MACKINNEY of Philadelphia read this paper in which they said that at the present time it was agreed by all urologists that high frequency destruction was the method of choice in the treatment of benign papilloma, and that it had no value in the treatment of true infiltrating carcinoma. Diagnosis must be established by a careful cystoscopic examination, or by the examination of portions of tissue passed or removed by special instruments. Since November, 1911, when they first employed high frequency destruction, they had observed 51 primary neoplasms of the bladder. A diagnosis of benign papilloma had been made in 22 cases, of papillary carcinoma in 3, and carcinoma in 26. High frequency destruction had been employed in 19 of the benign papillomata, in 3 cases of papillary carcinomata, and 7 cases of infiltrating carcinomata. In all cases of tumor of the bladder, hemorrhage was the predominating and frequently the only early symptom, the bleeding was usually marked and ceased as promptly as it began. With 3 exceptions the monopolar Oudin current, generated from a Wappler coil was employed and found perfectly satisfactory. The illumination was derived from a dry cell battery and the spark from the circuit. General anesthesia was not necessary, a satisfactory local anesthesia being obtained by the use of novocain. In nervous patients or patients with a highly sensitive urethra, treatment may be facilitated by a hypodermic of morphine administered one hour previously. A clinical cure was based upon freedom from symptoms, a clear urine, microscopically free from blood and pus, and the absence of any evidence of tumor by cystoscopic examination 3 months after the last treatment. Every patient was impressed with the possibility and danger of recurrences and advised to return at intervals of 6 months for cystoscopic examination.

Dr. B. A. THOMAS of Philadelphia said that to treat a papilloma of the bladder by any means other than high frequency sparking or electro-coagulation, must be regarded as a serious surgical error, poor judgment, or selfishness. On the other hand, any form of endovesical treatment for a malignant growth, pre-eminently sessile carcinoma, provided it was curable radically was the height of folly. His experience comprised not less than 69 tumors, varying in size from a pin-head to masses almost completely filling the bladder. Almost invariably bleeding had been a prominent factor, but fortunately, as a rule, the first effect of electro-coagulation was hemostatic. A few patients had been so exsanguinated as to require preliminary supporting measures. In one case with a hemoglobin of 19 per cent, two transfusions were done before undertaking the treatment of the tumor of the bladder. Without exception cure had resulted in each case of papilloma, also papillary carcinoma with a non-degenerated pedicle. In no case of sessile carcinoma or other malignant growth involving the bladder wall has cure been obtained. Both the Oudin and d'Arsonval currents have been employed by Thomas, and he prefers the former. It seemed to make little or no difference whether the current was degenerated by a static machine or a coil; the results were equally good with the latter.

Dr. JOHN L. LAIRD of Philadelphia said the the character of the bladder growth in relation to its amenability to this form of treatment was a serious consideration, the benign and the superficially malignant tumors being appropriate, the infiltrating malignant growths demanding immediate surgical intervention. The treatment of the various types of benign papillomata required a selection of the kind of current to be used. The interval between treatments was important and should be governed by three factors: viz., the extent of the bladder involvement, the type of current employed and the degree of reaction to the treatments. He wished to emphasize that all vesicle papillomata are potentially malignant and, therefore, early diagnosis and eradication are of the utmost importance. High frequency destruction was beyond doubt the method of choice. For the same reason, after an apparent cure, each case should be carefully followed for a possible recurrence. Some cases of severe and obstinate character require patience and frequently the result was unsatisfactory and disappointing; but the majority respond promptly with a result little short of miraculous.

Dr. EDWARD MARTIN of Philadelphia said in regard to the operative treatment of bladder tumors, by which he meant the cutting operation, those who observed and wished to hear from patients notice that to their astonishment the old operating cystoscope gives results in papilloma operation very much better than the open operation. Those who have a certain number of these

papilloma have observed a widespread recurrence after the operation and there seemed no adeuate explanation of this excepting the disturbance caused by gross traumatism. We had, first, the lesson that the local treament, nontraumatizing, was better and modern local treatment by desiccation was much better than by instrumentation. The second point he wishes to bring out was the innocuousness of this desiccation in the ordinary run of cases. For all practical purposes the majority of these people could go to their ordinary business. They had no further discomfort and their lives were not materially interfered with. When the cystoscopist was unable to decide as to the malignancy or the benign nature of the lesion, he felt that this desiccation treatment should be tried and resort to perhaps grosser methods of instrumentation follow.

Dr. H. M. CHRISTIAN of Philadelphia said that he wanted to emphasize the point made by Uhle and MacKinney that every so-called benign tumor of the bladder must be considered potentially malignant and that a man with a so-called benign tumor in his bladder had to all intents dynamite in that bladder. In cases on the borderline, where there was a chance he thought that the patient should be given the high frequency current. He wanted to empasize again the point which Dr. Uhle made of the importance of looking on sudden, inexplicable, rapidly disappearing hematuria, rapidly reappearing hematuria, with or without pain, as very significant of bladder tumor and requiring examination directly.

Dr. ALEXANDER RANDALL of Philadelphia said that he wished to call attention to the efficiency of electric fulguration of vesical papillomata (benign); the recognition of the ultimate and potential malignancy of all such growths and that in their early stage, therefore, while still benign, vesical papillomata represented precancerous state and by its prompt and early recognition and treatment we would be taking a definite step forward in the present campaign for the eradication of cancer.

Treatment of Empyema. — Dr. EDWARD MARTIN of Philadelphia read this paper, in which he said that in order to avoid infection from the skin a puncture was made through the skin, deep fascia and into the muscle by means of a cataract knife. The trocar was pushed into the pleural cavity, stopping when the resistance of the chest wall was no longer felt. The location of the pus thus having been determined, an incision 1½ inches long was made through the skin and a large trocar thrust into the pus cavity. The stylet was removed and a silver tube was passed through the canula. The canula was then withdrawn and the flanges of a tube were stitched to the skin by means of silver wire. The silver was not irritating to the tissues and provided against compression or kinking as was the case with a rubber tube. If necessary a cupping glass or suction apparatus could be intermittently applied to produce negative pressure. Pulmonary exercises were to be instituted early. A dressing dampened with mild antiseptic solution was applied over the tube. If there was much adhesion between the pleural layers, these should be freed through a large incision in the intercostal space.

Dr. JOHN H. JOPSON of Philadelphia said that his own practice had been in favor of the ordinary methods of drainage and following Richardson's advice to make large holes. We could do this operation early and painlessly on a child if we could carefully and systematically anesthetize everything down to the pleura. He believed we should do this under general anesthesia. Under local anesthesia if the patient was in bad condition. He liked to get a look into the chest and free light adhesions in the lungs in the early stage and remove large loose masses of lymph which would clog any tube and probably break down and disintegrate. If one could do that and introduce the tube, Dr. Martin advised, we were making a great advance.

Dr. JOHN DE V. SINGLEY of Pittsburgh said that as regarded breathing exercises in these cases of empyema, it had been his custom for years to have the patients use an ordinary football to blow into. The amount of pressure was limited only by the will of the patient and it could be carried out of doors, where he liked to keep these patients most of the time.

Dr. H. C. WELKER of Norristown said that he believed the keynote to success was a liberal separation of adhesions and breaking up of locules and serum that could not be gotten by the ordinary timid methods of opening up. Instead of that a liberal opening up and going up to the apices, remembering that the accumulation frequently extended to a point where we had no idea it was possible for it to extend.

Venous Thrombosis and Embolism: Its Cause, Significance and Consequences.—Dr. ANGUS MCLEAN of Detroit, Michigan, read this paper in which he said that although various causes had been assigned for thrombosis their experiments had shown that an infection or toxine was necessary to its production. In his series of 1610 laparotomies, 33 cases were followed by thrombosis or embolism. The embolus appeared on an average about two weeks after operation. The usual symptoms were chill, fever, and if the obstruction was near the surface, pain was a prominent symptom. As for treatment, when once the condition had developed, absolute rest, warmth and measures to encourage the venous circulation were indicated. In the case of a thrombus, absolute rest should be insisted upon as a precautionary measure against secondary embolism. This rest must be continued until the clot had had a chance to become thoroughly organized, a process which would usually take from 3 to 4 weeks.

Dr. EDWARD MARTIN of Philadelphia said that Dr. McLean's ingenious and yet simple explanation had corroborated the view that many surgeons had had that there must be an infectious basis in all these or nearly all these cases of thrombosis. We saw less of it now than we used to, particularly in the direction of the lung.

Treatment of Puerperal Infection and Septic Abortion. —Dr. JOHN M. FISHER of Philadelphia read this paper, saying that in cases of puerperal sepsis, the severity of the infection with the same microorganism even, varied in type from the most malignant, fatal in a few hours, to a type with symptoms so mild that in the absence of extraordinary precautions it might escape detection. He still believed alcohol to be of service in the treatment of profound toxemia characterized by feebleness of heart action, depression of the nervous centers, and the so-called typhoid states with either high or low temperature. The importance of eliminating toxic products through the excretory canals could be too strongly emphasized. The influence that the ingestion of water exercised on the skin and kidney was well understood. By whatever method administered it added to the volume of the circulation, raised blood pressure, improved the quality of the heart's action, promoted nutritive changes incident to constructive and destructive metamorphosis, diluted toxic products and promoted their elimination by its stimulating action on the kidney structure. The profession had been slow in estimating the value of outdoor life in tents or porches in the care of patients suffering from puerperal and other forms of sepsis. By the open-air treatment was meant the actual outdoor exposure of the patient and not merely her removal to a sun parlor or veranda with closed sides.

Prevention of Fecal Fistula in Suppurative Appendicitis. — Dr. DONALD GUTHRIE of Sayre read this paper, stating that his choice of incision was the muscle-splitting, or McBurney's. In those who had well defined abscesses lying near the mid-line a straight incision was made over the most prominent part of the mass. Wherever possible he inverted the stump, using catgut. Where this was impossible the cuff operation was done. An effort was made to further reinforce the field by tying in the cut meso-appendix. Drainage was afforded by large caliber soft rubber tubes placed as far from the head of the cecum as possible and removed by the end of the first week. Laxatives were never given until all drains had been removed. He had had 3 fecal fistulæ develop in 853 cases.

Dr. C. E. THOMSON of Scranton said that he always used gauze for drainage and allowed it to remain until it came away itself and always used linen thread for ligating the stump of the appendix.

Dr. G. M. DORRANCE of Philadelphia said that he must get hold of a different kind of appendicitis case from those spoken of by Dr. Guthrie. In a large number of his cases the appendix as well as the head of the cecum was gangrenous and came away when taken hold of by forceps. Therefore, he had a great many cases of fecal fistula. He always regarded these cases as favorable because they invariably got well.

Treatment of Cancer by the Use of Radium in Conjunction with Surgery.—Dr. GUY C. POUGHTON of Erie read this paper, saying that most of the cases of cancer in which radium treatment had been used had been inoperable cases, many almost moribund, and in this

type of cases radium treatment had achieved what no other treatment could do. He wished to emphasize that what was necessary now was co-operation rather than destructive criticism if we were to be able to establish the value of radium therapy in the treatment of malignant growths. Those who pioneered in any field had and expected to have hard work before them. The days of pioneering in work with radium were far from being past, yet this agent had been demonstrated and was being accepted more and more widely as a most valuable adjunct to the older methods of treatment. We would not replace surgery by radium therapy, but rather by combination with radium therapy make surgery more effective. The surgeon could remove the greater part of the malignant tissue, but the radium rays in suitable cases could go in and destroy all of the remaining malignant cells and in the treatment of even inoperable superficial cancers, carcinoma of the uterus, the prostate, the rectum, and the breast and in spindle celled or round celled, sarcoma, lymphosarcoma, in rodent ulcers, radium had been shown to be of definite value.

Dr. RUSSELL H. BOGGS of Pittsburgh said that radium had brought relief in many hopeless cases and many times extensive growths had disappeared and a clinical cure had been brought about. All inoperable cases should be radiated not only as a most excellent palliative measure, but in hope that the cases might either become operable or else that the disease might be arrested and the patient gain months or even years of comfortable life. He believed it was just as important to add Roentgen therapy to radium treatment as it was to use radium in conjunction with surgery, because it was a well-known fact that radium would destroy the cancer cells only at a distance of from 2 to 3 cm. from the tube.

Thursday, September 23—Third Day.

Surgical Treatment for Absent Vagina.—Dr. E. E. MONTGOMERY of Philadelphia read this paper, saying that he advised such patients not to have the operation but to accept the situation and give up the idea of marriage. Where conditions seemed to make it desirable that a vagina should be constructed it was important that it should have a lining of mucous membrane. The best plan was to line the constructed canal with a section of the intestine, either utilizing a portion of the ileum or of the rectum. He preferred the latter. The lower end of the rectum above the sphincter was utilized for the vagina and the rectal canal was reconstructed by loosening the rectum and bringing it down and making an anastomosis of the anus.

Late Results in Acute Appendicitis.—Dr. GEORGE P. MÜLLER of Philadelphia read this paper, stating that in order to determine the late results of operation for acute appendicitis an attempt had been made to follow up 200 consecutive cases operated upon by Dr. Frazier or himself and from these 117 replies had been received. Hernia occurred in 20 per cent of cases which had been drained, but in those not drained only one patient developed hernia. Nine patients suffered from adhesions, 6 of these having been drained and 3 not drained. Fourteen complained of indigestion, 8 of which were drainage cases. Seventeen patients complained of pain, but it was difficult to determine the cause. Constipation was rather common. The postoperative comfort of the patient depended upon prompt operation, the avoidance of cathartics before operation and the minimum of drainage.

Dr. JOHN A. KLUMP of Williamsport said that the best form of drainage in appendicitis was a soft rubber tube spirally split or fenestrated containing a strip of gauze loosely inserted. Experience had demonstrated that formerly entirely too much unnecessary drainage had been employed. The Fowler position following operation was of value.

Treatment of Undescended Testes.—Dr. JOHN H. GIBBON of Philadelphia read this paper saying that in the early months and years of life the mother or nurse should be instructed to gently draw down and push the testicle toward the bottom of the scrotum. If this failed by the third or fourth year his recommendation was that the Bevan operation should be performed. He had done this operation 22 times and had been surprised at the facility with which the organ could be carried into the scrotum. Eight of his patients were over 18 years of age.

Dr. R. G. LE CONTE of Philadelphia said that he was entirely in accord with the view expressed by Dr. Gibbon, but that the manipulations for relief of the condition in infancy should be carried out very gently or more harm than good might be done.

Free Transplantation of Fascia Lata in the Treatment of Inguinal Hernia.—Dr. FRANCIS T. STEWART of Philadelphia read this paper, saying that the free transplantation of fascia, contrary to preconceived notions, had proved to be almost uniformly successful, and for the very reasons that were brought to render fascia unsuitable for transplantation, *i. e.* its poor nourishment and its lowly situation in the scale of organized tissues. This method was especially called for when the hernia was large, recurrent, sliding or direct. The best place from which to obtain the fascia was from the region just below the outer portion of Poupart's ligament, after undermining the lower edge of the skin incision for exposing the inguinal canal. The transplant was immediately sutured with catgut to the under surface of the everted margins of the transversalis fascia. The edges of this fascia were then united over the transplant.

Dr. J. S. RODMAN of Philadelphia said that the recurrent cases were the most troublesome of inguinal hernias and it was here especially that the use of some material to strengthen the abdominal wall would seem to be called for. He believed that Dr. Stewart had chosen the best material of all to transplant. In operating for recurrence the most difficult problem was to restore the anatomy to something approximating the normal. This could usually be done with the Bassini technic, and, if transplantation was added to this, it would suffice to cure the majority of such cases.

The Public and the Profession.—Dr. HENRY B. FAVILL of Chicago read this address, saying that within the last few years the relation of the medical profession to the public had been undergoing radical change. Formerly the relation had been essentially individual. The physician had a definite service to perform in behalf of his patient and the small group related thereto. Important as that was, it was hedged about by restriction as to breadth of view, both for the physician and his clientele that were hampering to full development. Misconception as to the true value in medical service had led to such pettiness and superficiality as had given basis for hostile criticism. Medical science had risen almost wholly within the last half century. It was marvelous that its spirit and its method was as widely prevalent as it was in consideration of the fact that scientific teaching had been general only in the last 25 years. The profession was rapidly adapting itself to its more weighty function. It was dawning upon the public consciousness that the big thing in social affairs was the preservation of health. The place to focus attention was upon health, not sickness. With the advance in science, the possibilities of curing disease once established, were comparatively limited. It was imperative that the medical profession saw its opportunity and its obligation. The public had a right to expect leadership in this direction from physicians. The public, however, needed education as to what it meant, what could be done, and how. It must co-operate intelligently and strenuously. If the medical profession was to devote itself to the public weal with the energy and self-sacrifice that it had shown in its capacity as practitioners, it must be met by the public with recognition of its integrity of purpose and the paramount importance of the issue.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 7, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Wesley M. Carpenter Lecture: The Kinetic Drive: Its Phenomena and Its Control.—Dr. GEORGE W. CRILE of Cleveland delivered this lecture, in which he analyzed the mechanism of modern speeding in man, due not only to war but to industrial and commercial driving in peace, and related it to the speeding which was due to other stimuli such as infections, autointoxication, physical injury, etc. Since the entire process of speeding was that of the transformation of potential into kinetic energy, the state of increased energy transformation might fittingly be called the kinetic drive Dr. Crile stated that man was a mechanism—an automaton—whose primary work was the transformation of energy. By means of a system of organs especially adapted to this end, energy was stored in these organs during sleep which during consciousness, in response to environmental contacts, was transformed

into muscular action, into heat, or into the representations of muscular action, such as emotion, thought, or reasoning processes. Another result of energy transformation was the formation of acid by-products. The driving force which caused the transformation of energy within the organism was supplied by certain parts of the brain, while the organs which vary and control, accelerate or retard the driving force of the brain were the adrenals; the pacemaker of the kinetic system was the thyroid. The final act of energy transformation was performed by the muscles. The primary adaptive process within the brain, by which the driving force was created and sustained, was oxidation. If the blood were acid, oxygen could not be carried by the hemoglobin. Energy transformation depended therefore upon the maintenance of the alkalinity of the blood. Since energy transformation was accompanied by the formation of acid by-products the process demanded a mechanism by which these acid products could be neutralized and eliminated, which was met by the liver, the kidneys, and the lungs. If this system of organs adapted for the transformation of energy acted as a unit then every excessive excitant such as insomnia, excessive muscular action, extreme emotion, infection, foreign proteins, pregnancy, etc., should cause identical changes in the histological structure and the function of each organ concerned in the transformation of energy or in the neutralization and elimination of the consequent acid by-products, while in addition, intense and short and long continued activation by any of these agents should cause also identical acute and chronic diseases. Each of the above named excitants caused increased respiration, increase in the frequency and force of the heart beat, thirst, excitability, perspiration, increased acidity of the urine, and identical manifestations of fatigue and exhaustion. If the adrenals determined the driving force of the brain and if each activation of the kinetic system caused an increased output of adrenalin, then adrenalin alone would produce the basic phenomena caused by any excitant of energy transformation, and would produce identical histological lesions, and it did. In addition adrenalin given over a long period of time caused myocarditis, glycosuria, albuminuria, fatigue, and many symptoms of cardiovascular and cardiorenal disease. Dr. Crile showed pictures of Belgian refugees which illustrated the gross effect of the combination of extreme emotion and exertion on the facies and bearing of individuals, and also photographs showing the effect of various kinetic stimuli upon the brain, the adrenals, and the liver.

Dr. Crile then showed that if adrenalin caused identical phenomena with emotion, exertion, infection, and if, vice versa, these caused an increased output of adrenalin, we might infer that it was through increased mobilization of adrenalin that increased energy transformation was accomplished. And again, one would find that in the state of adrenalin deficiency the manifestation of energy transformation would be diminished. This was true, for after double adrenalectomy there was an increasing and finally a total loss of muscular power and of heat production. If the nerve supply of the adrenals were divided and an adequate adrenal stimulus applied, the output of adrenalin was not increased. On the other hand, if the nerves were intact and a large dose of morphia were previously given, then the application of an adequate stimulus caused no increased output of adrenalin. The adrenals were easily exhausted, but the efficiency of adrenalin might be increased by thyroid secretion. This belief was supported by the researches of Osterhaut, who found that iodine caused an increased permeability of living vegetable tissue to the passage of electricity and the impulses generated by the combination of adrenalin and oxygen were probably identical with electricity. In other words, iodine increased the efficiency of adrenalin. In this interrelation of brain, thyroid, and adrenals we had probably the master key to the automatic action of the body. The increased output of thyreoiodin by facilitating the transmission of electric currents through semi-permeable membranes increased the passage of nerve impulses and set the pace for energy conversion. In consequence the adrenals were driven to increased activity, and the increased adrenalin in turn excited the brain to greater activity, as a result of which an effect was produced which was equivalent to increased work of the sympathetic nervous system. Here, again, Dr. Crile showed photomicrographs and blood-pressure charts illustrating the kinetic action of iodine and adrenalin.

Dr. Crile next considered the methods by which the kinetic drive might be controlled and said that they had found that morphine controlled the rate of energy transformation in response to any stimulus, whether infection, emotion, injury, or Graves' disease. Alonzo Clark on empiric grounds made the daring innovation of treating peritonitis with opium, and even to-day we must concede that next to surgical treatment the administration of opium was the most efficient treatment for peritonitis. Dr. Crile, however, said he combined the administration of opium with surgical treatment in those cases only in which the kinetic drive threatened to kill the victim. In such cases a quick anociated operation under nitrous oxide, Fowler's position, huge hot packs, saline infusions, sodium bicarbonate and glucose, plus the Alonzo Clark opium treatment, in from 24 to 48 hours had given startlingly good results. The amount of opium must be determined not by quantity but by its effect on the kinetic drive; the respirations should be reduced from twelve to fifteen per minute. In any acute infection it would be reasonable to combine the use of opium to block the destructive kinetic drive and of alkalies to neutralize the excessive acid by-products. Lantern slides again illustrated the manner in which morphine, nitrous oxide, and alkalies conserved the energy of the kinetic organs.

While it was safe to block the kinetic drive by morphine in cases of acute injury or of acute infection, it was unsafe to use opium to block the effects of intense emotion, because of the tendency to a repetition of the dose with the resultant danger of habit formation. The emotional drive was best met by training and education leading to a philosophy of life that insulated the individual against destructive psychic stimuli. Whereas in the acute drive simple and direct control was possible, in the individual chronically driven by the stimuli of want, ambition, anger, jealousy, or grief the danger was that one or another of the overdriven organs or tissues might be permanently injured. Since the emotional states were most amenable to control it became obvious why these conditions had often been controlled by means apparently without therapeutic value, such as faith in the physician, travel, diversion, prayer, healing springs, philosophy. Innumerable men under the strain of a chronic drive were pushed beyond the narrow limits of safety by the added drive of grief, worry, or shame, with the result that their organs had become affected by the excessive energy transformation, and with these the physician met his greatest difficulties. The most typical of the kinetic diseases was Graves' disease. The principal phenomena of this disease were identical with the leading phenomena of any other kinetic drive of a corresponding degree of intensity and might be duplicated by fear, anger, sexual excitation, physical exertion, acute work, or acute infection. In fever there was a period of excessive kinetic drive which exactly corresponded to the kinetic drive in emotion and which signified the preparation of the organism for self-defense by chemical activity just as emotion signified the preparation of the organism for self-defense by motor activity. There was a marked likeness of the phenomena of the kinetic drive in Graves' disease to those of chronic infections, particularly of tuberculosis. This likeness was so marked that it was not at all uncommon to find diagnosticians of wide experience mistaking the one condition for the other. The following symptoms were common to both Graves' disease and tuberculosis —tachycardia, increased respiration, flushed face, tremors, persistent slight fever, nervousness, rapid loss of weight, digestive disturbance, hyperplasia of the thyroid and of the lymph glands, and enlargement of the heart. In tuberculosis as in Graves' disease the entire kinetic system was overdriven. Thus the kinetic theory of Grave's disease, infections, and emotion supplied a possible biological interpretation of the induction of these states, of their mutual resemblance, and of the method of their control. All were modified by rest, controllable by morphine temporarily, all caused increased hydrogen ionic concentration in the blood and therefore taxed the organs of acid neutralization. The increased respiratory rate in each of these conditions was accounted for by the specific stimulative effect of the increased hydrogen-iodine concentration of the blood in the respiratory center. If the acidity was increased so rapidly that neutralization could not keep pace with it, then nephritis might develop as an effect of the acid by-product upon the kidneys. Hence in emotion, infections, and Graves' disease, albumin and casts were frequently found in the urine and in extreme cases acute acidosis might develop. The acidosis in each instance was expressed by thirst. It was a significant fact that

lymphocytosis was commen to both Graves' disease and to the infections, these being the only diseases in which this phenomenon occurred. It was possible that the protective rôle played by the thyroid in infections was not that usually assigned to it, but was through the action of the thyroid secretion upon the lymphatics simultaneously with its effect upon the other defensive mechanisms. The speaker discussed further the analogy between diseases of the thyroid and diseases which among other organs involved the adrenals, which he showed was borne out by many clinical points. He demonstrated that each of these conditions bore an intimate relation to foreign protein activation and "nervous strain." Diabetes, arteriosclerosis, neurasthenia, and Bright's disease were due to the kinetic drive just as was Graves' disease. These conditions were all improved by rest, diversion, and dietetic control. It seemed to follow that a chronic disease which was made worse by increasing the kinetic drive would be improved by lessening the drive and would be improved temporarily by blocking the drive with morphine. A like result it would seem could be secured by breaking the connection between the brain and the thyroid and the adrenals by the excision of a portion of the thyroid and of the adrenals; and if still further blocking of brain impulses were required, by dividing the cervical sympathetics. After extensive experimentation on animals Dr. Crile said he had performed such operations fifteen times on a series of hopeless epileptics, patients with Raynaud's disease and with cardiovascular disease, and finally on a case of advanced diabetes. Ten institutional epileptics had been so treated, and while none had been cured, all made good operative recoveries and the severity and intervals of the attacks had been favorably influenced. Glycosuria in certain cases of Graves' disease had been lessened by operation. It was well known that where there was adrenal deficiency sugar tolerance was raised and that when there was thyroid deficiency the sugar tolerance was raised, while on the contrary excessive amounts of adrenalin or of thyroid extract mobilized sugar; therefore, in intractable diabetes, might it not be possible that diminution of the total mass of adrenals and thyroid might sufficiently increase sugar tolerance to assist in or actually cure the disease. Dr. Crile said he had so treated one patient who made a good operative recovery and whose urine had remained sugar free for three months with the exception of one day. This case was presented as a problem and not as a recommendation of the adoption of these measures in diabetes or other kinetic disease. Dr. Crile exhibited photomicrographs showing the identical end-results produced in the brains of humans by some of these kinetic diseases and of the brain, adrenals, and liver of a soldier who died as a result of a combination of several kinetic stimuli, principally emotion, exertion, and insomnia.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

WUNDHEILNUG MIT AETHERISCHEN OELEN. By Dr. DANIEL WAGNER. Published by Urban & Schwarzenberg, Berlin-Wien; 110 pages. Preis geb. M. 2.50.

ORTHOPÄDISCHE BEHANDLUNG KRIEGSVERWUNDETER. Von Prof. Dr. HANS SPITZY, und Dr. ALEXANDER HARTWICH. Published by Urban & Schwarzenberg; mit 144 textabbildungen; 214 pages. Preis geb. M. 7.

OPHTHALMOSCOPIC DIAGNOSIS FOR GENERAL PRACTITIONERS AND STUDENTS. By GEORGE W. JEAN, A.B., M.D. Published by E. B. Meyrowitz, Inc., London, New York, and Paris; sixty-eight illustrations; 123 pages.

MONOGRAPHS OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. No. 5. September 27, 1915. Composed and printed by The Waverly Press, Baltimore, Md.; 130 pages.

SYPHILIS AS A MODERN PROBLEM. By WILLIAM ALLEN PUSEY, M.D. Published by American Medical Association, Chicago; 129 pages.

MODERN BIOLOGIC THERAPEUSIS. Published by Medical Department of the Lederle Antitoxin Laboratories. Illustrated; 322 pages. Price, $1.00 postpaid; cloth binding.

Therapeutic Hints.

Treatment of Hypothyroidism.—In treating hypothyroidism Scott makes it a rule to test carefully the blood pressure before and during treatment. He states that hypothyroidism is usually associated with hypertension, the blood pressure generally being about 160 mm. to 170 mm., and that the dosage of thyroid extract may be safely increased; but in the case of hypotension the thyroid extract is apt to take badly. For overcoming this disability he recommends the giving of suprarenal extract as well and the careful watching of the blood pressure. This should be kept as near 140 mm. as possible. To get this result he gives about 10 grains of suprarenal extract daily and about 5 grains of thyroid extract.—*The Practitioner.*

Carbolic Paste for Routine Surgical Work.—Fleet Surgeon Martin of the British Navy has used the following as a first dressing, without any previous washing, in every sort of injury, such as compound fractures, and in conditions of sepsis, such as abscesses:

Hydrated wool fat, 6 parts.
Candle wax (or white beeswax), 1 part.
Carbolic acid, pure, 20 per cent.

After the "sting" of the first few minutes it gives more relief from pain in the case of burns than picric acid solution; it also gives better results. Infected wounds clean up; and compound fractures which were expected to suppurate and other wounds in which sepsis might be expected healed in a very remarkable way when dressed with this paste.—*Journal of the Royal Naval Medical Service.*

Phenol in Epidemic Meningitis.—Bellotti treated two cases of cerebrospinal meningitis with the following mixture:

℞ Phenol, 0.01 gram.
Morphine sulphate, 0.005 gram.
Aquæ destil., 1.0 gram.
M. (Sterilize.)

This mixture is administered hypodermically whenever the fever rises or the pains increase, care being taken, however, to avoid phenol poisoning.—*Gazzetta degli Ospedali e delle Cliniche.*

Emetine Subcutaneously for Endamebiasis.—Lyons advises small repeated injections of emetine as preferable to large single doses. The amebicidal action of ipecac or emetine reaches the amebas in the tissues through the circulation. The irritating effects of emetine are negligible when a dose of one-third of a grain is injected. The daily aggregate dosage should not exceed one grain for an ordinary case of amebic dysentery.—*American Journal Medical Sciences.*

In Chronic Cystitis.—Fullerton finds permanganate of potash 1 in 5,000, nitrate of silver 1 in 5,000, or sal antisepticus ʒij to the pint, of great service as lotions for washing out the bladder. He says that boric acid solution is too weak, but is better than nothing.—*Medical Press.*

Inunctions in Bronchitis.—Rachford finds the following efficacious in bronchial affections, especially in acute bronchitis in children:

℞ Guaiacol, ʒss.
Olei gaultheriae, ʒj.
Lanolin, ʒj.

M. Sig.: Rub about one teaspoonful into the chest twice daily.

THE VALUE OF SCIENTIFIC DOUBT IN SURGICAL DIAGNOSIS.*

BY JOHN B. ROBERTS, M.D.,

PHILADELPHIA.

Massive Intrahepatic Hematoma from Rupture of Hepatic Vein.—I operated last winter upon a colored man of 51 years who had fallen and struck the epigastric region against a step. When seen by me a few hours after the accident he was suffering intense pain in the upper abdomen, and the muscles of the anterior abdominal wall were rigidly contracted. There was only a slightly increased pulse rate, with normal respirations. The temperature was somewhat subnormal. He had, however, the peculiar ashy hue of pain and shock, recognizable even in the negro countenance.

My diagnosis was rupture of stomach or intestine and I advised immediate operation because his evident suffering, although morphine and atropine had been given hypodermically, proved the existence of a serious lesion.

On opening the abdomen I found a little free blood in the peritoneal cavity, extravasated blood within the gastrohepatic omentum and the transverse mesocolon, and also under the peritoneum covering the attached side of the colon. No rupture of stomach or bowel was discovered. Liver, spleen, intestines, gall-bladder, and urinary bladder seemed free from injury. Some blood was discovered behind the peritoneum near the pancreas; but this and the other extravasations were not accompanied by evidence of free bleeding anywhere.

The abdominal wound was therefore closed, and my diagnosis of ruptured hollow viscus remained unconfirmed. The man died as the operation was finished, either from shock or from ether poisoning due to careless administration.

Autopsy at first showed nothing definite, except the findings seen at the operation, although the abdominal and thoracic contents were removed. After further search for the hemorrhage's source had been considered almost unnecessary, I split open the removed liver and found a blood clot of about six fluid ounces lying in a cavity within the right lobe of the liver at its posterior part, close to the entrance of the hepatic veins into the cava. (See Figs. 1, 2 and 3.) There were small subpleural extravasations and extravasations under the kidney capsules.

This intrahepatic rupture with hematoma, a rare lesion, was an unthought-of injury. Its preoperative diagnosis was impossible, but its possibility should have been suspected when I saw before death bloody infiltration in the gastrohepatic omentum. The largest of the three veins was torn about an inch from the cava by an opening about $\frac{1}{8}$-inch long.

Dr. John A. Kolmer found the liver to be markedly fatty with slight perilobular fibrosis, and no evidence of *Trepanoma pallidum*. The cavity containing the soft dark clot was irregularly lobulated; at the widest part it was about 3 inches in diameter.

Horse-Shoe Kidney Simulating Perforating Appendicitis.—In the same month I was asked to see a boy of 16 years with appendicitis. He had been seized with severe abdominal pain in the morning with vomiting. He had very little if any abdominal rigidity; but there was a very palpable mass in the right inguinal region a little lower than McBurney's point and some increase in leucocyte count. Temperature and pulse were not far from normal.

I would have delayed operation for further observation of the patient, had not the superficial and readily palpable mass convinced me that perforation of an inflamed appendix had occurred, and that the suppurating organ was plastered by adhesive lymph against the internal surface of the belly wall and that it was probably surrounded by an abscess.

After hasty sterilization of the skin, the abdomen was opened; and an unadherent normal looking appendix removed. It was lying immediately over the right lower pole of a horse-shoe kidney. The left segment of the double kidney was felt with my fingers in the abdomen. It was attached to the kidney visible under the appendix by a flat fibrous band about an inch in width. This connecting bridge lay across the spinal column at about the level of the lumbosacral intervertebral cartilage and joined the two renal organs at their lower ends.

The four-inch vertical wound in the rectus was closed; and no trouble ensued, except delay in union by reason of superficial suppuration. Microscopic examination showed, according to Dr. Kolmer's report, evidence of chronic interstitial appendicitis.

To find a horseshoe kidney so low in the abdominopelvic cavity is rather rare. For it to stimulate an appendicitis abscess is a combination of symptoms of very exceptional occurrence. The history of this patient proves that hasty diagnoses are not always reliable. Dr. M. S. Kakels has reported (MEDICAL RECORD, December 21, 1912) an instance of "Sacral Kidney Simulating Acute Appendicitis."

Reflection upon the unusual causes of diagnostic error in these two cases has induced me to make some statements on the value of a doubting mind in surgical practice, and to confess the unreliability of my snap diagnoses.

A certain surgical author has recently said "Diagnosis by intuition is a rapid method of reaching a wrong conclusion." Some experiences within the last few months have convinced me that this statement and that of another master, who said "None of us is infallible, not even the youngest," deserve to claim our respectful consideration.

*Read before the College of Physicians of Philadelphia, June 2, 1915.

Doubt may be present in a surgeon's mind because of insufficiency of personal knowledge, a careless application of the knowledge he possesses, a limitation of time, due to the urgency of symptoms, or an absence of general professional knowledge

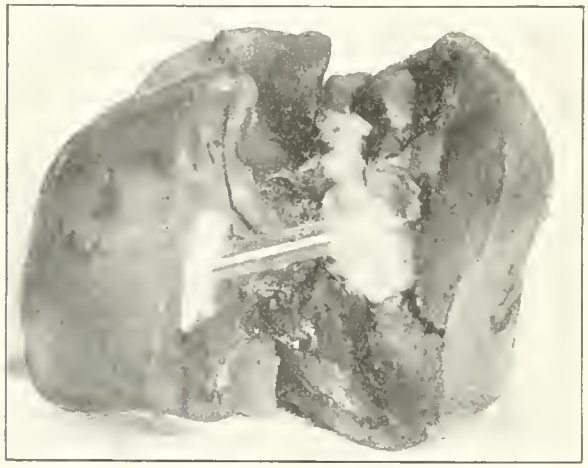

FIG. 1.—Traumatic rupture of fatty and somewhat cirrhotic liver, upper surface. Cavity, which was occupied by a massive intrahepatic hematoma, is filled wtih cotton, incised right lobe held apart by a glass tube.

of the physiology and anatomy of the human organism. I have on various occasions hesitated to operate from all of these causes, but am hoping that the second mentioned, carelessness, has been an infrequent influence.

The tendency nowadays seems to be to operate when in doubt without devoting much time to exercising one's faculties in diagnostic queries. A usual gynecological notice on bulletin boards seems to scoffers to be "abdominal section," often abbreviated to "section." In former days "section"

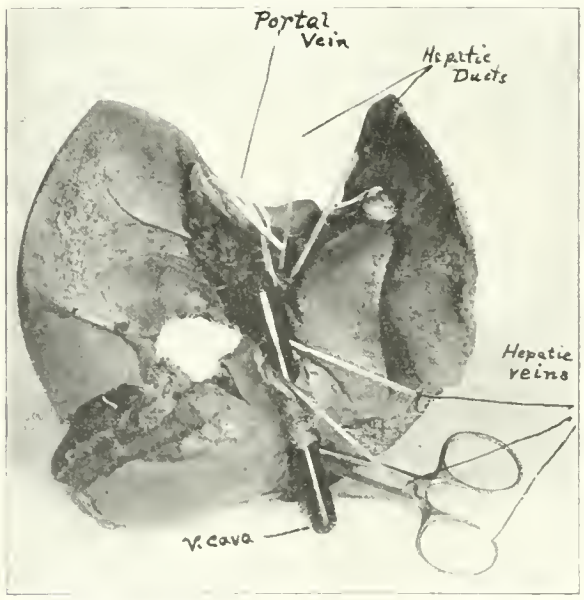

FIG. 2.—Lower surface of same liver in which a massive traumatic intrahepatic hematoma was found at the back of the right lobe; it was from rupture of the largest hepatic vein about an inch from its opening into the vena cava. Black rubber tube in vena cava; hemostatic forceps in injured hepatic vein; twisted wire in portal vein; match sticks in hepatic ducts and the two uninjured hepatic veins.

meant, I believe, "an autopsy." Now it is used, I suspect, to cover "reserved diagnosis," and not a multitude of sins of omission in clinical examination.

A medical visitor from Europe a few years ago wrote that in America patients were ever in such a hurry that they were unwilling to accept medical treatment for their ailments, but insisted on being subjected to surgical operations. All thoughtful lovers of the science of surgery must recognize this attitude of mind in many of their patients. It is a reflexion of the imaginary safety of aseptic technique under all circumstances in all conditions of men. In my earlier surgical life I smelled the odor of rotting pus every morning as soon as the door of the surgical ward was opened for my admission. Many ounces of pus did I day after day press out of cavities in infected tissues surrounding the necrotic bones of open fractures, while the injured men either gradually faded until amputation opened the way to slow months of convalescence, or quickly dropped into the grave from septic infarctions or repeated secondary hemorrhages.

No one therefore more than I realizes the ineffaceable debt owed to Lister; but that debt does not close my mind to the needless mutilations and unnecessary deaths due to the insane rush to operative therapeusis by the ignorant public, induced thereto because the saving grace of doubt seldom

FIG. 3.—An ordinary glass tumbler containing clot, removed from the interior of the liver, due to traumatic rupture of the most posterior hepatic vein. The clot measured about 6 fluid ounces.

enters into the minds of some dogmatists of surgical art.

John Hunter's definition of surgery was that it consisted in curing a disease rather than in the removal of it by mechanical means. An earlier writer put the same thought in Sanscrit thus: "Only the association of medicine with surgery forms the perfect physician. The physician who is deficient in the knowledge of one of these branches resembles a bird with but one wing" (Ayur veda, Art of Life).

Thomas Vicary, "sergeant Chyrurgion" to Henry the Eighth, explains in the "Profitable Treatise of Anatomy" of 1548 "what properties and conditions a man must have before he be a perfect Chirurgion." "The first (I sayde) he ought to be learned and that he knowe his principles, not onely in Chirurgerie but also in Phisicke, that he may the better defende his Surgery; Also he ought to be seene in natural Philosophie, and in Grammer, that he speak congruitie in Logike, that teacheth him to proue his proportions with good reason. In Rethorike, that teacheth him to speak seemely and eloquently; also in Theorike, that teacheth him to know thinges naturall, and not naturall, and thinges agaynst Nature. Also he must know the Anatomie, for al Authors write against those Surgions that

worke in mans body not knowing the Anatomie, for they be likened to a blind man that cutteth in a vine tree, for he taketh more or lesse than he ought to doo."

Many present day operators would find it difficult to "defende their Chirurgerie" upon the principles of "phisicke" and of "chirurgerie" by speaking in "logike, that teacheth them to proue their proportions with good reason." Some, indeed, in my opinion, when cutting patients do take away more than they "ought to doo."

The mind that admits no doubt is a closed door; useful in emergency at times, I admit, but dangerous to the public. Its dogmatism often quickly brings the wavering patient under its sway and may thus occasionally save a man from the risks of delay born of timidity. Who, however, can number the fatalities due to hasty diagnoses upon which unnecessary operations have been undertaken?

The relative safety of aseptic wounds has led to a wide distribution of operative surgery, but has taken a great toll in deaths by its encouragement of hasty diagnoses and an unhesitating resort to mutilating therapeusis.

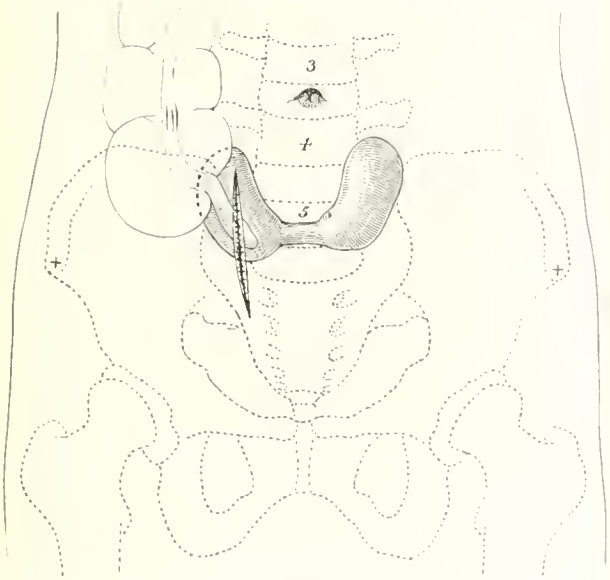

FIG. 4.—Congenital horseshoe sacral kidney simulating appendicitis.

I once heard an enthusiastic surgeon, when asked how much liquid paraffin he gave to test the presence of obstinate intestinal stasis, reply "as much as she will take." The indefiniteness of the response was equal to the illogical determination that removal of the entire colon was the only cure. The effect of a dose, based on the patient's willingness to swallow, was apparently the only proof of the medical incurability of her probable static constipation.

One might as well practice surgery on the theory that a pain in the abdomen requires ablation of the appendix, whenever the patient will permit an incision to be made in his abdominal wall.

Too much trepidation in the surgeon's mental equipment is not what I suggest, but a caretaking investigation, before the diagnosis is announced, based on a doubting thoughtful review of personal and family history, and of physical and psychic symptoms. Then a balancing of the operative risks with the dangers of a reasonable delay should influence the surgeon's resort to immediate operation.

Fractures.—The present day addiction to operative treatment of fractures is a case in point. A brilliant young surgeon, for instance, recently informed me of his position on this question in these words: "I operate on every case of fracture of the

FIG. 5.—Spiral fracture of right femur occurring on shipboard. M. D., boy of twelve years. Treated by Buck's traction method; *x*-ray taken soon after injury.

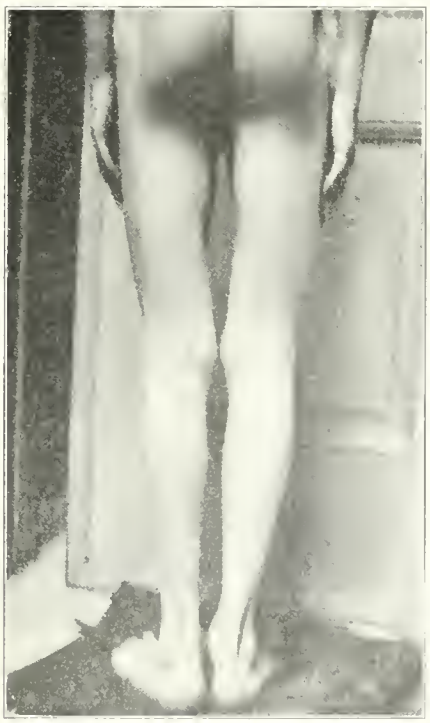

FIG. 6.—Spiral fracture of right femur. Boy, M. D., 12 years old, treated by Buck's traction method. There is scarcely any shortening, but perhaps a little outward turning. Photograph taken about 20 months after the injury.

femur, most cases of fracture of the tibia, etc.,

etc." There is no suggestion of possible doubt in that statement. Hence I dislike it. It is not scientific, it is simply dogmatic. The subcutaneous fractures, which require blood-shedding operative treatment, are those which cannot be reduced properly otherwise and those in which the reduction cannot be maintained except by direct fixation.

Fig. 7.—Spiral fracture of the shaft of the left femur, with a large triangular fragment detached. A. D., 16 years.

The wisdom of doubt about such general resort to operative intervention in fractures has been impressed upon me by experiences like the following: A boy of twelve years fell on shipboard and sustained a very oblique fracture of the left femoral shaft in its lower half. For a week he was treated in the ship at sea on a sofa berth by traction, then encased from umbilicus to ankle in plaster of Paris, and transported over a hundred miles by train to a hospital. There he was treated by Dr. John H. Gibbon by Buck's extension method. About twenty months after the accident, he was examined by me a few days ago and it was difficult to tell which leg had been injured. He had perfect function and so little shortening that it was difficult to determine whether it exceeded a quarter inch. The boy was active, straight in spine, and was the captain of the junior tennis team at school.

Fig. 8.—A. D., 16 years, after treatment by Buck's traction method. There is slight shortening of the left lower extremity, easily corrected by a pad under the heel inside the shoe. Photograph taken about 18 months after the injury.

About 18 months ago a tall young man, sixteen years old, standing on a coasting sled, was obliged to jump off. He received a spiral fracture of the shaft of the femur, with the separation of a triangular piece of bone in addition to the chief line of fracture. He was treated with Buck's traction by Dr. T. F. Branson and Dr. E. B. Hodge. The fracture was so long that the callus made his thigh bone feel like a massive column within the integument of his thigh. I examined him carefully recently, finding about a half inch shortening, a slight deviation laterally of the spine, easily corrected by elevation of the heel inside the shoe, and perfect function.

Fig. 9.—Inversion fracture of tibia and fibula at the ankle in a man, showing little deformity in the *x*-ray plate. Anterior view. The deformity was marked and overcome only with difficulty under ether.

Both of these patients, in my opinion, have been treated more scientifically and more reasonably than if their parents had been induced by an operative "addict" to permit fixation with metal plates. The type of fracture in both instances was that which is claimed to often need direct fixation to get good results. The anxiety, anesthesia risk, and other unnecessary possibilities of harm appertaining to open blood letting treatment was not justified in either of these cases. They are mentioned here because I had opportunity of seeing the cases during

and after treatment, and in fact, had some part in the management of them.

Advocates of the open treatment of fractures as superior to the non-operative routine base much of their argument on the reliability of radiography as

Fig. 10.—Inversion fracture of tibia and fibula at the ankle in a man, showing little deformity in the *x*-ray plate. Lateral view. The clinical deformity, inversion and retraction of foot with impaction, was marked and was overcome with some difficulty under ether.

indicative of offending displacement. Radiograms are of exceeding value in confirming the existence of fracture in doubtful injuries; but the degree of displacement may be in some degree factitious both affirmatively and negatively. The position of the tube, its distance from the limb and the distance of the examined bone from the photographic plate vary the shadow picture greatly.

The radiologist as well as the surgeon must be ever on his guard to avoid errors from false readings of the shadow values. Recently I have treated several fractures, the radiograms of which were reported to show good position, when clinical inspection showed to anatomical eyes that there was marked displacement. This was so notwithstanding that the *x*-ray plates were taken in two planes and read by an expert in skiagraphy. One case was a man with inversion fracture of the tibial and fibular malleoli with backward and inward displacement of the foot, requiring great force under ether to break up displacement and obtain reconstruction. The other was a greenstick fracture of radial and ulnar shafts that required complete fracture of both infractions to restore the *gross* contour of the forearm.

Other Operative Risks.—Some years ago I was consulted by a woman about twenty years old who said that she had been informed that she had had appendicitis and that now was the time for an interval removal of the offending organ. She wanted my opinion before submitting. After careful investigation I replied that an interval operation was justifiable if a competent surgeon was employed. I heard no more of the patient until some months later, when I learned that she had died, apparently of hemorrhage, a few hours after operation done in a hospital.

A few weeks ago I operated on a young man in desperate condition from tight intestinal constrictions secondary to an appendicitis operation with removal of the organ performed a half year previously. He fortunately recovered, though there was opaque serum in the peritoneal cavity and much congestion of the strangulated ileum.

I recently saw a man with bronchopneumonia which developed after an exploration of the abdominal cavity for possible intestinal wounds following a knife thrust into the belly wall. No visceral injury was found. Many sequelæ of abdominal operation such as hemorrhage, intestinal obstruction, and ether poisoning will probably be remembered by this audience.

I met some years ago in an elevator a vigorous looking man who called me by name and proved he was a man who would have had a leg amputated a couple of years before, had I not urged his surgeon to keep applying more skin grafts. The oldest patient I ever had with appendicitis died at about 85 years from pneumonia. I had attended him about six years before with a well marked appendicitis and advised non-operative treatment. The decision was evidently judicious.

Unnecessary Mutilation of Women.—A few weeks ago a woman with a small almond-sized growth in one breast came to me in great trepidation because after a bruise she had discovered the little nodule. She was about 38 years old and had consulted a surgeon who insisted that she must lose the entire

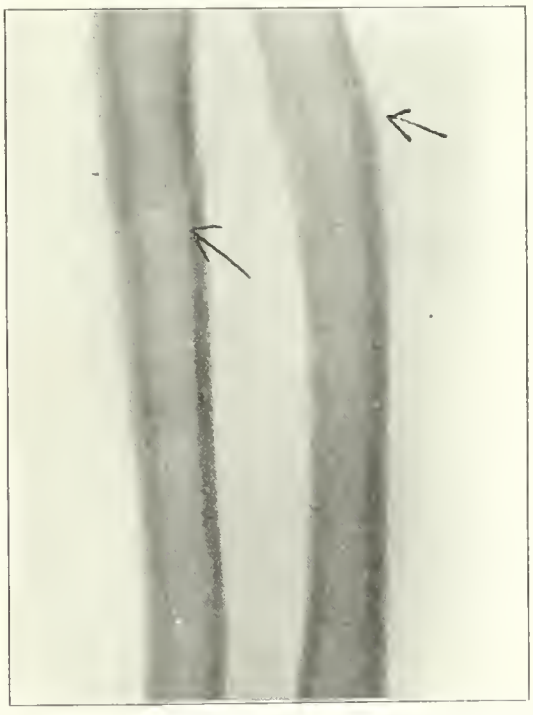

Fig. 11.—Fracture of both bones of the forearm (greenstick) in a boy, showing little deformity; though marked clinical deformity requiring refracture under ether was present.

breast by amputation. My opinion was given that the nodule should be removed by operation and subjected to microscopic study before such a disaster came upon her. I excised with a few sweeps of the knife the growth and a considerable block of sur-

rounding gland tissue. Dr. John A. Kolmer reported that the growth was a fibro-cystadenoma with no evidences of malignancy. I append his report in full:

"I beg to report that sections of the tumor of the mammary gland which you recently submitted for examination show the histological structure of a fibro-cystadenoma with no evidences of malignancy The fibroma predominates and is of a hard variety. I suspected chronic cystic mastitis, but there is not sufficient evidence of the chronic inflammation. There is in my opinion a numerical increase in the glands and many are cystic due I believe to a constriction of their ducts by the increased amount of fibrous tissue. As already stated careful examination of these glands and ducts does not disclose any evidence of malignancy."

About $2\frac{1}{2}$ years ago a school girl of 17 years found a small nodule in her breast. I acted in a similar manner. In this case the opinion of a skilled microscopist was that there was some evidence of potential malignancy in the histological structure of the sections made. His opinion was supported by two other microscopists. A third to whom I submitted the sections believed that the growth was one of those improperly considered malignant. After much thought, I concluded to excise the scar of the little incision and remove a good sized wedge of the breast. The patient has been seen since at intervals without any evidence of return and reported to me orally a few days ago that nothing had appeared to suggest trouble.

Surely in both these cases the results have shown that a doubting mind and a willingness to use pathology and clinical experience as coordinate assistants are better attributes of a surgeon than an operative dictum that potential trouble shall lead to immediate sacrifice of organs despite the risks physical and the agonies psychic of patient and family.

Enucleation of Healthy Tonsils a Wrong.—The bloody sacrifice of entire tonsils which has recently been offered to the écraseur, tonsil punch, and other pharyngeal instruments seems to me unworthy of scientific medicine. Who knows for certain the value or the worthlessness of these lymphoid organs in the little child's throat? I see frequently a healthy, fine looking mother of several children, who in early life was my patient with middle-ear inflammation and enlarged tonsils. I advised shaving off the redundant tonsillar tissue with a tonsillotome as was the custom of the time. The parents never consented and therefore no operation was done. The child grew to womanhood and married. She has had no trouble with ears or throat but is unusually healthy in every way.

A few years ago one of her children died in five days with violent infection shown at autopsy in brain and spinal cord, only a few weeks after removal of adenoids, which had caused ear trouble, and the total ablation of the healthiest tonsils one is likely to see. Might not the retention of the unoffending lymphoid tissue between the pillars of the fauces have acted as a sieve to restrain such a lethal invasion of the specific organism of anterior-poliomyelitis? Surgeons do not scoop out normal lymph nodes of groin, axilla, or neck when a patient has an infection of toe, hand, or lip, unless there is present evidence of secondary infection of major importance. I fear that the tonsil may have also a protective function even if it may be an atrium for invading microorganisms. Operators should remember that the vestibule door of a house keeps out sneak thieves, though it may occasionally admit an unwelcome guest.

The tonsils are not unnecessary organs, even if laryngologists do tell us they are; appendices are often valuable additions to books and may be to the human animal. The suprarenal body, the carotid gland, the hypophysis, the thymus, the thyroid were recently organs of unrecognized activities. Their value to the economy is now established.

"Potential" dangers should not always lead us to take operative risks. Sometimes the etherizer, the trained nurse, the pathologist's microscope, the chemist's vial, the surgeon himself, or the contingent circumstances of the patient, the time, the place of operation, or the "perversity of inanimate things" may be more dangerous than aberrant cells, the invading microorganism, or the neurotic crisis.

"Potential" is a word to scare patients, but not wise surgeons. Arsenic, strychnine, mercury, opium and alcohol are potential poisons, but shall we fear them and never use their power? Must we throw them out of our armamentarium? A sharp knife in the hands of a clever cutter is potentially more dangerous than a doubting mind in the skull of a thoughtful surgeon who believes that all problems cannot be solved by a keen edge alone.

Many fractures result in good function and good anatomical result without running the risk of ether poisoning, septic contamination, or amputation; some breast nodules are not the precursors of horrid death by malignant ulceration and metastasis; some appendices remain anatomically valuable, perhaps physiologically so; an ovary may often look sclerosed to the ignorant eye without needing removal. Nature does not require the kidney of a biped vertebrate to be rigidly glued to his back bone; all pains in the lower right quadrant of the abdomen are not due to the vermiform appendix; spinal puncture may be more deadly than a doubtful injury to the cerebrum.

"Potential" malignity has caused the sacrifice of a good many female breasts; "potential" perforative appendicitis has led to unnecessary abdominal sections; "potential" tonsillar atria of infection have deprived many children of tonsils that were doing no harm.

Greatly would some of us have increased our operative lists had we stitched to the lumbar muscle all the loose kidneys referred to us for operation. The number of so-called sclerosed ovaries removed twenty years ago during the bloody operative crusade against unrecognized neuroses will never be known. The loss of wages, limbs, and even lives from the present furor for fixing with metal supports fractures of the extremities is hard to estimate.

The scientific mind must be a doubting one, but it must not be too conservative to novelty and progress. My thesis is that a surgeon should be open to conviction, but not carried away by enthusiasm born of illogical hasty conclusions, based on superficial study, half understood physiological processes, and other unsafe premises.

It would be easy to relate case after case in which a doubting attitude of the consultant or the better knowledge of the family physician has saved a family from the anxiety inseparable from operative attack on person and pocket book; and perhaps preserved ovary, breast, limb, and even life.

Surgery must be regarded as a science, a part of all science, and not a mere art, if we who pose

as surgical specialists wish to rank with the wise men of the earth.

To some of my hearers this paper may seem like a conservative cry that denotes a static surgical mind not receptive to the advances of a progressive science. I earnestly hope my doubting mind on present day problems may not be closed yet awhile to scientific enthusiasm and serious study.

I, however, freely admit my dubious mental attitude to dogmatists in surgery, science, and religion. They tire me and fill me with doubt. The Creator seems wiser than most authors of the latest fads in operative therapeusis. The human animal needs, as a rule, tonsils, vermiform appendix, mammary glands, aye and his colon. Pathological deviations from normal in these and other organs may often be corrected by other methods than excision. A painful eye should not always be plucked out and cast from one. It is pleasanter and safer to wear correcting lenses. So also is it cheaper, pleasanter and safer to drink water and take exercise than to drink wine and ride in an automobile; and later have one's colon extirpated.

313 South Seventeenth Street.

BONE GRAFTING AND ARTHROPLASTY.*

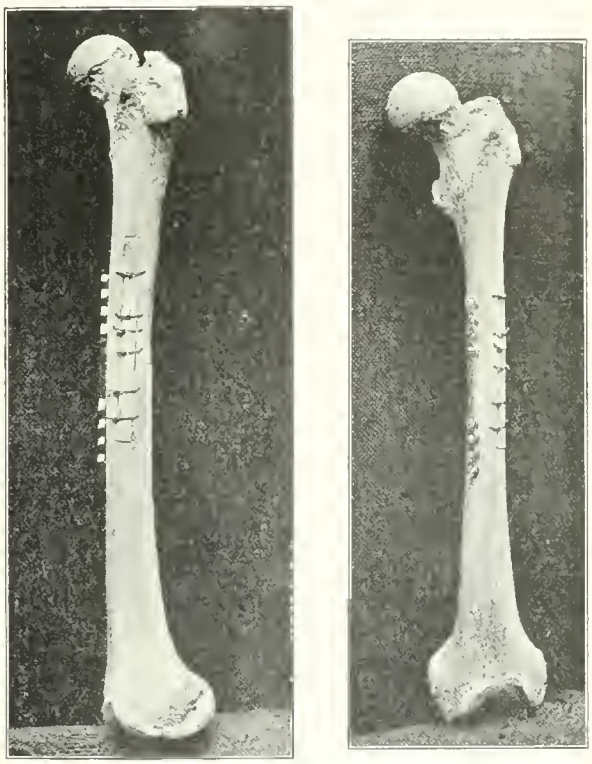
By GEORGE H. SEXSMITH, M.D.,

BAYONNE, N. J.

ATTENDING SURGEON, BAYONNE HOSPITAL.

While Listerism which revolutionized surgery has existed for many years, it has only during the last decade been perfected to the point where it was considered safe to treat fractures by the open method, and for a lesser period of time has the surgeon considered it advisable or safe to invade the synovial or joint cavities except in extreme cases, where from the character of the conditions with failure there was nothing to lose and with success there was at least something to gain. This tardiness of the application of surgery to the bones and joints has been due to two principal causes: First, the general recognition of the liability of sepsis with its disastrous results in this particular line of surgery. This together with the terrible outcome seen in the infected compound fractures and accidentally opened joints was sufficient to deter the most courageous and daring surgeon from converting the simple into a compound fracture or from opening the joint for operative procedures. Second, that immediately following the birth of asepsis which made possible the development of abdominal, thoracic, and intracranial operations, the profession gave practically its undivided attention to the development of first abdominal and later thoracic and intracranial surgery, and only when the pathology of the curgical lesions of these parts had become comparatively well understood and their treatment made practical did the surgeons of the world take up the development of the field that had to do with the bones and joints, whose pathology and repair up to the present time are only beginning to be understood; although probably in no line of surgery has there ever been such progress made in so short a period as in the one under consideration.

We have seen the gradual evolution of the open treatment of fractures where the good results of a few of the pioneers encouraged others to take up this line of work, and with many, probably through inferior technique or judgment in handling their cases, the results were unsatisfactory. These failures led to strenuous objections by some, disagreement and doubt by others as to the advisability of the open treatment of fractures. So remained the status of this plan of treatment of fractures until the results of the successful were multiplied and the mistakes of the unsuccessful were pointed out. I believe we are indebted to Sir Arbuthnot Lane of London more than any other surgeon for a perfected technique, which, if followed out, will insure success in a large percentage of cases. Since the advent of his methods of operation, the open treatment of fractures has increased tremendously, and is still increasing. I have referred to the high point of development of asepsis as one of the principal causes of success in bone surgery. I want here to emphasize this particular point. There is no line of surgery where anything short of the most perfect possible asepsis is so liable to give such deplorable results. This is generally acknowledged by surgeons doing this line of work at the present time, but who have in the past been doing general surgery. The requirements for successful bone and joint surgery are: First, the most perfect possible asepsis; second, a well planned general surgical technique; third, a thorough understanding of the anatomical conditions, and fourth, a mechanical turn of mind.



Figs. 1 and 2.—A comparison of the metal plate with screws, etc., with the inlay bone graft method of treating fractures.

Mr. Lane's success has been phenomenal, especially as in his treatment of fractures, he has at all times used the metal plate, screws, wires, nails, etc., with all the possible objectionable influences produced by the use of these foreign substances. Although with his technique and perfect asepsis, he has in a large percentage of his cases been successful in bringing about union of fragments as well as well formed and useful parts, nevertheless I contend that the introduction into the body of these foreign elements, although possibly not producing

*Read before the New Jersey State Medical Society.

an infection, must to the average mind appear as contrary to nature. Again, this claim for the successful use of these same appliances in the treatment of fractures in the hands of the average bone surgeon during the last five years cannot be made,

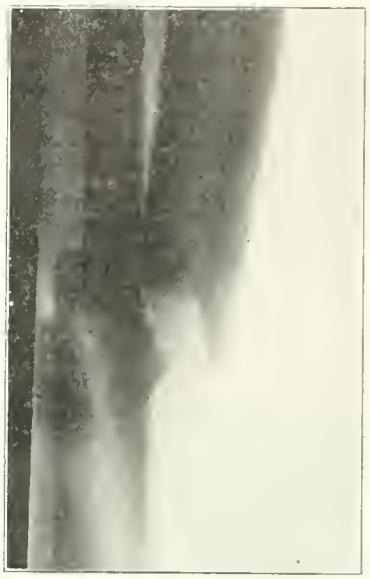


Fig. 3.—Case 1. Compound fracture of tibia and fibula; reduction under anæsthetic and application of plaster of Paris cast with no infection or rise of temperature, with complete failure of union at the end of six weeks, at which time I operated, using the inlay bone graft in the tibia, holding the graft in place with kangaroo tendon ligatures, which were passed through small drill holes, the lowest point of which entered the medullary canal at the junction of the bone graft with the fragments. With a freshening of the ends of the fragments of the fibula which were brought in apposition with some difficulty, no internal appliance was required to hold them in apposition

as in from thirty to fifty per cent. of such operations, either immediately following or at some later period, these plates and screws have been the cause

Fig. 4.—Case 1. Ten weeks after operation in which about the only evidence visible of a bone graft having been used is the light markings representing the drill holes. The patient resumed his ordinary occupation at the end of twelve weeks.

of a sufficient disturbance to necessitate their removal such disturbance being generally due to infection and occasionally to pain, the latter caused by a loosening of the screws and a displacement of the plates, producing pressure on the soft tissues. It is a well-known fact that a wire encircling a bone or used to hold fractured bones in apposition, if under tension will cause a disintegration of even the hardest bone tissue within a very few days sufficient to cause a loosening of the wire to an extent that will prevent its being of much use as a support of the bone fragments which it surrounds. This is also true where nails or screws are used in the treatment of fractures. Every surgeon who has had any experience in removing these nails or screws even within one week after they have been applied will appreciate the truth of this statement. This is one of the strongest pleas that could be given against the use of metal substances in the treatment of fractures. The mere fact that even the most flinty bone tissues will not tolerate the presence of such foreign materials even under moderate tension without disintegrating within so short a time is evidence that in their use we are working contrary to physiological principles.

While the progress made in bone surgery during

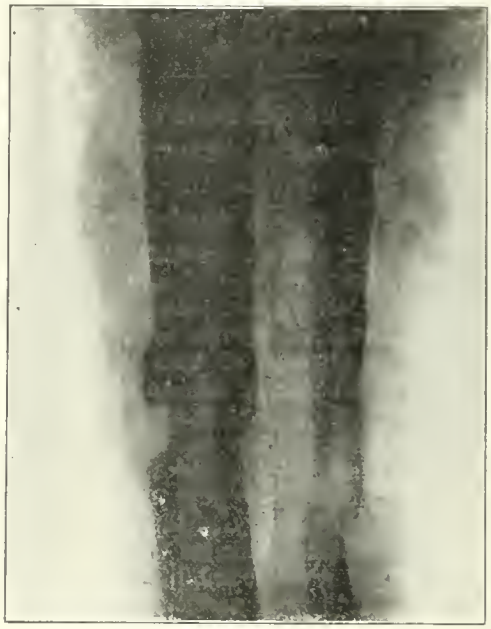

Fig. 5.—Case II. Compound fracture of tibia and fibula with use of the inlay bone graft in both bones, the bone graft used in case of fibula being very narrow, was held in place by several kangaroo tendon ligatures which were passed completely around the bone, drill holes not being thought advisable because of their weakening effect on so small a bone. Patient able to resume ordinary occupation at the end of fourteen weeks.

the last five or six years has on the whole been of great benefit to humanity, and without doubt has been instrumental in bringing about better results in the treatment of the various forms of fractures met with, at the same time I believe the pendulum has swung too far in the direction of operative treatment. This is not an unusual experience in surgery, as we have found in the past that any new surgical procedures which have seemed to promise great things have often been applied in certain cases without any very definite understanding or particular study as to positive indications for such operations.

In bone surgery, the open treatment simplifies matters very much. It does away with the study of anatomy and of the different types of fractures. The diagnosis is made by the radiologist and the surgeon has to think but little about the plan of treatment as it is always the same—simply the application of the plates, nails, or screws. In other words, he becomes only a mechanic. These offenses

against common sense, deplorable as they may be, especially for the patient, are nothing in comparison to the harm done in cases of accidents, and these are by no means rare. While the patient with a moderately deformed arm or shortened leg, yet with good functional results, will probably all his life blame the surgeon who treated the fracture, still this is of less importance and a small matter compared to a septic infection with possible disability or death following an open operation performed too often by those poorly prepared. I must enter a decided protest then against the adoption of the general treatment of fractures by the open method. I believe that, with the proper knowledge of anatomy and the use of common sense in the conservative treatment of fractures, good functional results can be obtained in at least ninety per cent. of the cases without the use of the open treatment, and in not over five per cent. of the cases so treated will we have non-union. If these state-

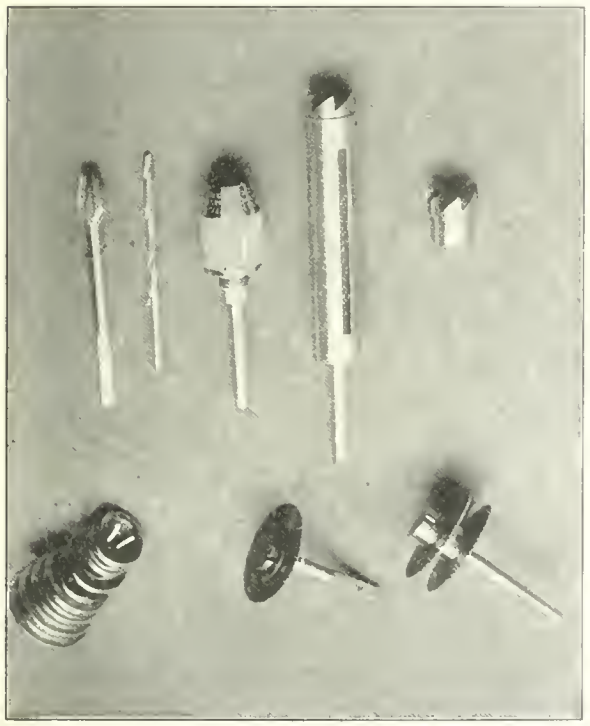

Fig. 6.—Some of the most important appliances devised by Albee used in connection with an electric motor in bone surgery.

ments are true, then the surgeon who is treating practically all forms of fractures by the open method with all the dangers accompanying this treatment, is certainly jeopardizing the health and life of his patients to an extent which is hardly excusable.

We are taught in our surgical treatises that a fracture is a solution of the continuity of the bone. This, in fact, is only a part of the injury produced. We have, rather, in a fracture an injury which is, in a large majority of instances, a complex traumatic condition with a severe and in many cases most serious injury to the soft tissues, and in some cases the injury to the soft parts is of more importance than that of the bone. The injury of the muscles, nerves, and blood-vessels, which amounts in reality to a lacerating and crushing, causes a lowering of the vitality and power of resistance to infection of the parts injured, as well as the formation of blood clots, this combination producing one of the most favorable culture-media that could be found; and this condition, even with the most rigid aseptic precautions and in the hands of the most capable surgeon, must often give bad results on account of the septic complications following opera-

Fig. 7.—Case No. III. Pott's disease of the spine causing complete disability. Operation by the Albee method splitting the spinous processes of seven vertebræ and inserting a graft from the crest of the tibia with complete relief of disability, patient resuming his regular occupation at the end of twelve weeks. This operation, I believe, gives a larger percentage of complete, permanent and satisfactory results than any other now being performed on the bony frame.

Fig. 8.—Case III. Showing result of osteoplastic operation on patient shown in Fig. 7

tion. I believe that no fracture, compound or otherwise, should be operated upon with the use of the plate, bone graft, or any other internal appliance now in use for holding the fragments in place before seven to ten days have elapsed from the time

of the injury, at the end of which period nature has had an opportunity to reorganize the tissues and fortify itself against the invasion of the poisonous germs which so often are present if from no other source than the skin, as in all operative procedures. The only exceptions that I would make to this rule are: First, fractures in or about the joints where the early readjustment of fragments is important to prevent as far as possible the formation of callus, which so often interferes with the future free action of the joint, and secondly, in cases where the soft parts, especially the blood-vessels and nerves, are in danger of being injured by the pressure of displaced fragments. In such fractures, we are justified in taking the added risk of infection caused by early operation.

The experiments which have been made on animals by the application of foreign substances in bone surgery are not a true test of the usefulness and practicability of this form of treatment of fractures, as in such cases we have not to deal with the lacerated and bruised tissues nor the hemorrhage with the production of blood clots which we have in an ordinary fracture, and necessarily the results in these cases, so far as septic conditions are concerned, ought to be very much better.

If at the end of seven to ten days from the time of the fracture of a bone, open treatment is found to be necessary because of the inability to reduce the fracture, or, if reduced, to hold the fragments in proper relation to each other to give good alignment and functional results, one should use the greatest amount of care in cutting down upon the parts to produce as little injury as possible to the soft tissues; and after reduction, if the fragments will remain in their normal position, one should avoid the use of any forms of internal appliance, as the presence of all such appliances, if of foreign material, will militate against the formation of callus and act to prevent or delay union, as well as to favor the production of septic conditions. In the treatment of recent fractures the use of the plate will give a larger percentage of good results than in the case of old ununited fractures, where the ends of the fragments extending back at least an inch have become sclerosed, and as a result the osteogenetic elements have been lessened in their activity, and the bone cells are degenerated as well as lessened in number. This unnatural condition of the ends of the fragments, together with the injurious effects of the foreign appliances used, acts most unfavorably on the formation of bone callus. If we employ the inlay bone graft, we have an entirely healthy bony tissue covered by periosteum which in itself is capable of producing the osteogenetic elements necessary for the healing process without any of the detrimental influences present when the plates or screws, etc., are applied. In making this graft we use the twin saws to remove a section not less than six to eight inches in length, the longer portion of the graft being taken from the proximal fragment, and then when separated from its bed, it is slid down into the groove formed by the removal of the smaller graft from the distal fragment, bridging over the point of apposition of the fragments which have been reduced. We have in the use of the bone graft several of the important requirements which are fixation, stimulation of osteogenesis on the part of the fragments, and an osteogenetic bridge connecting the active bone in each fragment back of the sclerosed areas. The bone graft is the only means of fulfilling these requirements which are all essential or necessary in order to secure union. The plate furnishes but one of these and that is fixation, and at the same time, it causes absorption and disintegration of the bone and favors sepsis, while the bone graft acts to prevent the invasion of the poisonous germs. The intramedullary bone dowl gives good results and has possibly the one advantage of having a greater holding power, still I believe the inlay graft as used by Albee is superior in that one has the periosteum, solid bone tissue, and medullary substance of the graft immediately in contact with the same elements in the fragments, which is not the case when the dowl is used; and again, in the case of ununited fracture, one is able to get well beyond the sclerosed bone in the fragments with the inlay graft which is most important, but is quite impossible with the intermedullary splint.

In the treatment of Pott's disease, which until the last two years has been most unsuccessful, we have at the present time, a method which seems to promise, if properly applied, positive and permanent relief in this most disabling and unfortunate condition. The old expression, "The man without backbone is of but little use in the world," can be fully appreciated by those suffering from tuberculosis of the spinal column or Pott's disease. Patients suffering from this disease give us a picture that is most deplorable, and while the suffering experienced by them is not so great as in some other diseased conditions, nevertheless, there is probably no disability produced by disease of the bony frame which causes such marked feelings of helplessness and discouragement. Until the time of the development of the operations bearing the names of their originators, Albee and Hibbs, there was but little encouragement offered in the treatments of this disease. While the Hibbs operation has in many cases, given good results, it hardly seems as practical and certain as the one performed by Dr. Albee. This latter consists in a splitting of the spinous processes of the diseased vertebræ as well as one or two of the spinous processes of the sound vertebræ above and below, and in the fracturing of the half of the split spinous processes, always on the same side, and inserting a bone graft taken from the crest of the tibia, pressing the graft well down into the gutter made as above described and holding it in place by suturing over it the ligamentous tissue immediately adjacent to the divided spinous processes. This operation gives anywhere from twelve to twenty points of apposition, according to the number of spinous processes split, between fresh and healthy bone surfaces, a most ideal condition for rapid and complete bony union, necessarily causing a perfect and permanent ankylosis of the vertebræ included in the operative field.

The immobilization of any part of the body affected by tuberculosis has been known to be one of the principal factors in bringing about a cure or at least a cessation in the progress of the disease for a great many years; still until the development of the above named operations, no means had been found by which such immobilization of the spinal column could be produced. To Hibbs and Albee is due great credit for the origination of these plans of immobilization which give practically one hundred per cent. of cures, transforming the disabled and discouraged individual into a useful and desirable member of society, making it possible for him to resume his ordinary occupations in life, and all of this without jeopardizing the patient's life or

health, as these operations are not particularly dangerous except in so far as in all bone surgery the element of sepsis is concerned. The favorable results are noticed and expressed very frequently by the patient within a week from the time of operation when he seems to feel a certain relief from the support produced by the insertion of the splint, and in the majority of such cases the patients are able to be about without any mechanical support within from eight to twelve weeks, with no return or symptoms of the disability experienced before the operation.

Arthroplasty.—While we have had reports of efforts having been made in the past to produce movable joints from those ankylosed, there seem to have been no marked successes in this line, or at least in very few cases, until within the last few years. Dr. John D. Murphy more than any other man has developed this particular operation to a point of perfection which has made it possible in a

Fig. 9.—Case IV. Showing the position of the limbs in relation to the body and each other. Front view. In the formation of the condyles of the femur and the fauces on the head of the tibia, a slight variation could readily produce limbs that would not stand the test of the plumb line.

Fig. 10.—Case IV. Same as Fig. 9, side view.

Fig. 11.—Case IV. Shows the flexion possible in left knee, also scar due to a slough of the skin and adipose tissue of the lower portion of the U-shaped flap, which so often occurs in this particular flap in this operation.

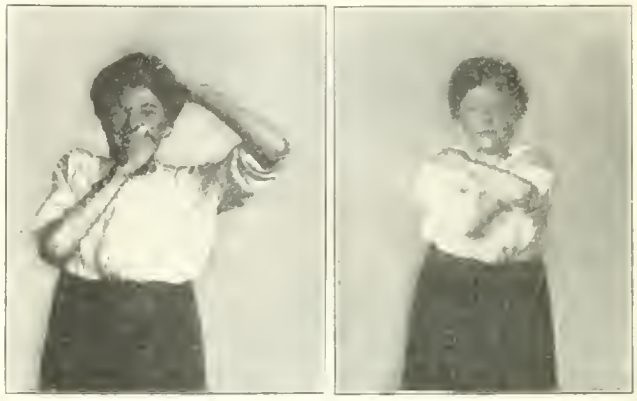
Fig. 12.—Case IV. Shows the flexion possible in right knee, in which the lateral curved incisions were used with absence of scar from sloughing. (See page 780.)

good percentage of cases operated upon to give movable, useful, weight-bearing joints. Of the ankylosed joints, we find three particular divisions —bony, cartilaginous, and fibrous. Certain restrictions in joint motions may be produced by diseased and contracted periarticular, ligamentous, and capsular conditions, and we also may have extra-articular interference of motion.

I show here to-day a patient who suffered a metastatic arthritis of both knee joints with a resulting complete double ankylosis, and on whom I operated during 1913. Figs. 9 to 12 show the different positions made possible for the patient to assume following arthroplastic operations for relief of complete bony ankylosis of both knee joints which had existed for three years, during the most of which time the patient had remained in bed because of an inability to walk and on account of her weight with the ordinary assistance to readily change her position. The joints were ankylosed in practically complete extension. On account of the injury produced by the forcible breaking of the ankylosis in the joints at two different times by an osteopath with the patient under an anesthetic, there was almost a complete absence of the semblance of joints. The femur and tibia, when chiseled apart at the time of operation, in both cases presented practically square surfaces, from which had to be formed parts resembling as nearly as possible the normal joint surfaces. Following the Murphy method, the ankylosed patellæ were turned turtle. The pedicled flap method was used in these operations. She now has movable, painless, weight-bearing joints. This patient weighs 250 pounds, and is able to attend to her usual occupation, going about the streets alone doing her own shopping, etc., with no complaint as to pain or unusual fatigue. With a patient weighing 250 pounds, one could have no better proof of the practicability of the arthroplastic operation than in this one before you.

The main principle in this operation consists of an interposition between the bones of some substance that will prevent bony union. Many different forms of foreign material have been used but without permanent success on account of the disintegration or absorption of that which has been interposed between the denuded bone ends. The best substance to interpose between the joint-forming bony surfaces which has been tried is the pedicled flap consisting of the fatty and capsular tissues from either one or both sides of the joint operated upon. Tissue from other portions of the body, especially the fascia lata, has been resected and interposed between the denuded bones, but has been found less efficacious, especially in the weight-bearing joints. The general causes for most of the failures have been insufficient or defective flaps, a failure in the proper removal of capsule and ligaments, the improper formation of the joint surfaces, infection, and pain or sensitiveness on motion after operation. It is hard to say which one of these elements is the most important. With a failure in any one of these principal points, one is almost certain to have, if not a returning ankylosis, at least a joint far from the normal and one that may give greater disability and pain than existed before the operation. One who has undertaken this operation on a completely ankylosed knee-joint and has found himself face to face with two large, flat, bony surfaces after chiseling apart the femur and tibia, there remaining no semblance of the original articular surfaces, certainly feels a great responsibility when he undertakes with chisel and mallet the formation of surfaces on the ends of these two bones which must be almost exactly the counterpart of the natural surfaces, to give legs that will stand the test of the plumb line and joints with anything like free and smooth motion.

To meet these requirements one must have a removal of the required amount of bone to allow of the interposition of the flaps, which, if not sufficient, will produce pressure and necessarily a sloughing of the interposed tissues, and if too much, will give



FIGS. 13 AND 14.—Case V. Showing the ability to flex the joints following an arthroplastic operation for an ankylosis of both elbows which had existed for a period of four years, the joints having been ankylosed in complete extension, making it impossible for the patient to feed herself, dress her hair or upper part of body. The pedicled flaps were used in these operations.

a loose and flail-like, useless joint; the ever-necessary intercondyloid ridge on the head of the tibia,

FIG. 15.—Showing my appliances for the reformation of joint surfaces in arthroplastic operations for ankylosed hip joints; these are, I believe, superior in that they are applicable to the various sizes of parts met with in these operations. These appliances are used with a motor.

with the proper formation of the intercondyloid notch on the end of the femur, both of which are important, and must be accurate to prevent lateral luxation; the proper formation of the flap or flaps and their interposition so as to cover every part

of the raw bony surfaces; and careful management of the ankylosed patella, which means the interposition of a flap between its raw surface and that of the femur, or the separating of the vastus internus and externus from the rectus muscle some distance above the joint, and the freeing to some extent of the ligamentum patellæ, making it possible to turn the patella upside down, bringing the smooth anterior surface in apposition with the denuded femur. All this, together with the ever-existing danger of sepsis, makes to my mind one of the most trying operations that we have. Murphy claims: first, that perfectly movable, normally functioning joints with sliding and rotary motions can be and have been produced; second, a new synovial membrane is formed with fluid which resembles synovial fluid; third, these joints support full weight and traction; fourth, they are painless, once the process of repair is complete. These four conditions I am able to prove in the case of one of my patients, whose history, with pictures of result, is given above.

THE NEGLECT OF INJURIES TO THE NOSE FROM FOOTBALL.

By D. BRYSON DELAVAN, M.D.,
NEW YORK.
PROFESSOR OF LARYNGOLOGY, NEW YORK POLYCLINIC.

The weight of evidence in favor of the proper use of athletics by the young is overwhelming. Unfortunately, however, the securing of agreeable and exhilarating exercise is always attended with risk. Thus water and winter sports, horsemanship, hunting, mountaineering, and all athletic games offer well-known possibilities of accident.

It should certainly be the endeavor of all interested in practical athletics to secure the best and most thorough training with the least physical injury to those trained. Without question, injuries which threaten lifelong disability should be vigorously guarded against; or, having occurred, should be at once recognized, their importance appreciated, and the best possible measures taken for their relief.

I desire to call attention to one form of injury common under many circumstances, but especially apt to occur in football and, perhaps, boxing, namely, fractures of the nose. From the prominence of its position the nose is especially vulnerable. Owing to the peculiarity of its structure, blows of moderate force are not liable to result in serious harm. Greater violence may cause injuries which are extensive and complex, difficult to remedy if neglected and serious as to ultimate results. Following such injuries, not only may the external contour of the nose be deformed and the countenance thus disfigured, but displacements of the interior framework may result in permanent obstruction to nasal respiration with its attendant evils.

The processes of repair after nasal fracture are very rapid. Often a few days will suffice to bring about a union of the displaced fragments sufficiently firm to oppose their easy replacement; while complete union is often accomplished within a fortnight. Meanwhile inflammatory thickening of the adjacent soft parts adds another serious difficulty to the effective management of the case. Without question the grand opportunity for securing the best results is presented immediately after the accident, within a period of hours rather than of days, if possible, before edema and swelling have obscured the situation, and adhesion of the displaced fragments has begun to take place.

During the football season injuries to the nose are common. Such accidents are apt to be accepted as more or less inevitable and the cases dismissed as of trivial importance compared with joint injuries likely to interfere with the action of the limbs and, therefore, temporarily impair the value of the player. Comparatively few cases report to the specialist immediately after the accident has taken place. Several weeks will often have elapsed before the patient presents himself. Meanwhile the fractured fragments have reunited to such an extent that it is impossible to separate them without the exertion of force. To replace them would require an operation.

A by no means negligible proportion of life-long nasal deformities and their consequences of respiratory obstruction, reflex irritations and sinus lesions immediate and remote, have originated through the failure of those interested to realize the importance of nasal traumatisms and the great necessity for their early recognition and prompt treatment. Many patients have been subjected to permanent disability and suffering when with proper management at the right moment the nose might have been restored to a condition sufficiently normal to have admitted of the full performance of all of its natural functions.

Cases almost without number might be quoted in illustration of this proposition. The following, however, will sufficiently answer the purpose:

A. B., aged 17, a vigorous young athlete, pupil at a large preparatory school, received a blow upon the nose during a game of football. The blow was immediately followed by severe pain, considerable bleeding, and slight displacement of the external and lower part of the nasal prominence. The patient was examined by the gymnastic trainer of the school, and also by the local physician, and was advised by them that no serious injury had been sustained. Instead of improving, however, the condition grew steadily worse, and two weeks later the boy consulted me in New York. It was then found that the bridge of the nose had been fractured and the septum fractured and dislocated. The tissues over the bridge of the nose were still swollen. There was a slight depression in the middle line of the nose just below the lower margin of the bridge. On examining the anterior region of the nasal cavity, both sides were found completely occluded by large swellings which extended from both sides of the nasal septum and completely filled the spaces adjacent to them. These swellings were soft and elastic, and pressure upon them plainly indicated the presence of fluid within. In other words they represented an abscess of the nasal septum.

This was at once opened and a considerable quantity of pus evacuated. The posterior superior part of the septal cartilage had been extensively perforated, sufficiently so as to create a slight sinking of the normal line of the nose. The cavity of the abscess was thoroughly cleansed, and several strands of drainage material passed through from one side of the septum to the other. Treatment customary in such cases was instituted, from the acute conditions and was followed by speedy and uneventful recovery, although the septum was perforated and permanently weakened and a marked depression in the external contour of the nose remained.

Having for a long time been impressed with the

*Read before the Section in Laryngology of the New York Academy of Medicine, October 27, 1915.

lack of care often paid to such cases, I wrote to the principal of the school in which this patient was a pupil, calling his attention to the case in hand, and asking him to make suggestions upon the subject. A courteous and appreciative letter was received in reply, in which the writer stated that in this particular case the presence of the injury had been promptly recognized and the boy placed in the hands of the best physician available. He wished to know what better could be done. I replied stating that the treatment of fractures of the nose in general belonged to a department by itself, more or less outside of the realm of the ordinary practice of surgery. The average general surgeon may be found to have paid comparatively little attention to it. Even among rhinologists, on the other hand, there are some who are not proficient in this particular kind of work.

That traumatisms of the nose should be left to the judgment of the ordinary trainer or to the average local practitioner is a mistalke all too often illustrated in the experience of every man interested in the study of rhinology, and is obviously wrong. The consequences of these accidents are so far reaching and so disastrous to the future welfare of the victim that no ordinary pains taken to prevent them should be considered too great.

It would seem that if the school were situated sufficiently near a large city for cases of nasal injury to be sent to town, then, in the absence of skilled aid nearer home, some arrangement should be made with the best specialist available in this department by which the boys could be referred to him, their injuries treated, and proper advice given them at the earliest possible moment. Where this could not be done on account of the situation of the school, the best surgeon in the vicinity should be stimulated to make especial study of this class of injuries, giving himself the benefit of special courses of instruction under the guidance of the most successful teachers whose services he could command.

While both of these suggestions might entail some inconvenience to all concerned, the advantages to be derived from them would far outweigh any objection. In the case of universities, colleges and schools situated in, or within reach of, cities well equipped with well trained physicians no excuse would exist for the students not to receive the best of care at the hands of men interested in the subject and of accredited experience and skill. It should be made emphatically clear to all concerned —patients, parents, teachers, trainers, and physicians—that nasal injuries are important, that they require prompt and very skillful attention, and that they are not to be treated with unconcern and neglect.

40 East Forty-first Street.

THE ELECTRO-MECHANICAL TREATMENT OF GENITOURINARY DISEASES.

By WILLIAM BENHAM SNOW, M.D.,

NEW YORK.

The differential consideration of the uses of electrical currents in medicine embraces three effects as derived from the electrical currents or modalities having different qualities or conditions. The variations include (1) *the electrolytic effect* as produced by the constant or galvanic current; (2) *thermic effects*, as produced most effectively by the high frequency currents; and (3) the *mechanical effects*, as produced most effectively by the static currents, but also by the sinusoidal and faradic induced currents, and the constant current interrupted. The *mechanical effects* of the static wave current and other static modalities are the effects that will be considered in this paper for the treatment of a class of genitourinary affections to which it is adapted.

There are two fundamental principles to be established as premises upon which the treatment of inflammation depends, whether of the genitourinary tract or elsewhere, as follows:

1. Wherever local injury or irritation of tissue occurs, either from accident, the presence of infection, or other disturbance of metabolism, swelling, with the establishment of local *stasis*, results as a consequence. Except in the cases of walled-in local infection the resolution by drainage of the tissues so infiltrated is essential to the promotion of prompt restoration of metabolism with removal of the pain due to pressure, and relief from an existing inflammatory process.

2. For the relief from, or resolution of local stasis forced drainage of infiltrated tissues with the removal of swelling or stasis by a mechanical *vis a tergo* is required, which will effectually express the accumulation from the lymph spaces, without causing irritation.

Upon the recognition of these two principles must stand or fall the establishment of the success of the methods I am about to describe.

In the past and even to the present time the relation of stasis to inflammation does not seem to have been fully recognized from this point of view. The first proposition does not seem to have been seriously considered nor the second adopted. Whether this is because no adequate means of relieving stasis had been found or because the importance of its removal was not recognized, is not for me to say. The methods employed for the treatment of local inflammation, it would seem, have been disposed to recognize the inflammatory process as a whole, as a part of the working of the *vis medicatrix naturæ*.

It may be readily understood how error could have been established in early times. Progress, however, has gradually developed methods of treatment which look to the softening of induration, even where pus processes are present. Manual massage, strapping, to prevent and possibly to reduce swelling, bandaging, and the application of heat and other methods of inducing hyperemia—all means of variously effecting a resumption of circulation—have become recognized methods. That none of these, however, has proved entirely adequate is evident from the ruling attitude toward the results of treatment.

Massage, while relieving swelling in subacute or chronic inflammation, is not permissible over sensitive areas, because a small degree of external mechanical pressure and manipulation, though it may to a degree reduce the swelling present, is contraindicated, and because the irritation produced tends to act as an added cause for a return of the swelling. Only when employed with the greatest gentleness and skill, working from the margin toward the more prominent parts of a swelling, can massage be effective in acute inflammation. As applied to the prostate gland the effect of the manipulation is first to empty the contents of the gland through the natural channels, but not to the same

extent to relieve the infiltration from the lymph spaces; and except with great care and skill, little progress is made.

The application of heat by various electrical methods or by radiant light or irrigation with hot-water flushing is disposed to widen the channels of the arterial circulation and possibly of the lymphatic circulation as well, thereby favoring the drainage of the engorged tissues, but is not adequate for the relief or reestablishment of circulation, when any degree of hardness or tension exists; because the tension or hardness present is too great to permit the opening of the lymph channels by efforts to establish hyperemia.

The only natural means for overcoming local areas of induration or stasis is by the recurrent pressure of the heart's impulse against the indurated wall, which is entirely inadequate, or by the final breaking through of the accumulating pus in a walled-in cavity, which last is followed by a relief of pressure and drainage of the pus cavity.

In the instance of the heart's action against an accumulated induration, the tendency is rather to increase than to diminish the swelling until collateral channels are established.

Strapping or the use of bandages applied early to prevent, or in order to turn the circulation off through other channels than to the site of inflammation, tends to prevent an enlargement of the field of stasis. When stasis is once established it is gradually followed by the development of hyperplasia which becoming organized remains as a persistent source of pressure. This is the unfortunate sequela when inflammatory processes are left to nature.

The presence of fibrin in and about the structures of joints in synovitis, and about the sheath of nerves when local neuritis has been unrelieved, or elsewhere, as in the conditions under consideration, results in the establishment of chronic inflammation. The various disturbances of metabolism, relative to the extent of accumulation around the joints, or neuritic pains from pressure of a thickened nerve sheath, or edema from occlusion of veins, as in variocele or in prostatic hypertrophy, are the effects of failure to resolve the infiltrating exudations in the early stages of an inflammatory process. That the exudations may be promptly forced onward through the lymph channels in the acute stage, without causing irritation even in the most sensitive and painful conditions, as in a sprained ankle, acute epididymitis, or a tender prostate gland is easily demonstrated by administration of the static currents.

No one recognizes more acutely than I do that the profession has been led erroneously into the notion that the static electrical current is a therapeutic myth, *which it is not.* This sentiment exists only in the minds of those not familiar with the effects of the methods employed. However, it can be shown that acute conditions which have presented an obstacle to successful treatment by other methods, yield to one or another of the static methods.

The modus operandi of the most valuable current employed in therapeutics—the static wave current—in effecting resolution of infiltration and exudation may be explained as largely due to the fact that it is a one-pole method of administration, whereby the patient, seated upon an insulated platform, is successively charged and discharged when the other side of the machine is connected to the earth. The alternate charge is followed by a discharge at the spark-gap and passage of the current to the earth. The patient receiving the charge passively as a condenser—as a Leyden jar—receives enough charge of the current to overcome the resistance of the spark-gap between the two terminal balls of the machine, when the current escapes as it passes from the surface of the body to the place of discharge, it passes from within outward inducing cell contraction of the mass of tissue over which an electrode is placed. By regulating the size of the electrode and the length of the spark-gap it is possible to control the local effect—regulating it to the condition under treatment.

If the part is extremely sensitive and the metal electrode placed against the surface is small the spark-gap should be relatively small and *vice versa.* In this way it is possible by the successive contraction of the tissue to empty from infiltrated areas the foreign content, thereby producing mechanical drainage of the involved tissue. This is a cardinal principle in the treatment of local inflammatory conditions and is applicable to every part of the human body from a closed tear duct in epiphera, to the relief of a synovitis of the knee or hip joint. Likewise it is capable of draining every accessible gland in the human body, including the great glands. The liver, in hypertrophic cirrhosis and the large malarial spleen are effectively drained and reduced by this method. It will be readily seen that under this condition of things it is possible to disengorge the prostate gland, the seminal vesicles, or the inflammatory exudations present with epididymitis.

Prostatitis may be effectually treated by this method in either acute or chronic cases. My observations have convinced me that hyperplasia rarely occurs in chronic prostatitis. In upward of three hundred cases that I have had under observation, myomata have been found in not more than ten per cent. In the chronic infiltrated gland in the aged it is surprising to what extent by persistent treatment it is possible to bring the gland back, in most cases, to normal dimensions, thereby effecting great relief from the low grade inflammatory process which is interfering with the function of the gland as well as causing pressure upon the urethra interfering with the normal free passage of fluids from the bladder.

The method employed for the relief of prostatic infiltration makes use of a suitable electrode which is placed in position in the rectum and held closely in contact with the enlarged gland. This is usually accomplished with the patient lying upon his side upon a suitable folding chair. An insulated handle is attached to the electrode which is held in position by a suitable device or by the hand of the patient. The more acute the condition the more marked the relief at the first application and the degree of permanent relief which follows the first few administrations. The persistence of the reduction is always a surprise to those not familiar with the method. The usual plan is to administer the current daily for the first five days, making each seance for twenty minutes and regulating the length of the spark-gap to the condition. When the gland is very sensitive the spark-gap employed must be relatively short, regulating it by the amount of pain produced with the successive contractions, the depth of the contractions being always relative to the length of the spark-gap. The

spark-gap need never be made longer than four inches in any case and the sensation of throbbing or pulsation will be relative to the firmness or tension of the gland, and will be synchronous with the discharge at the spark-gap. As the gland becomes gradually normal the pulsations become less and less perceptible to the patient.

The relief afforded by these administrations is evidenced first by a sense of lightness or diminished weight in the perineum, and by the diminished frequency of micturition both in the day and at night.

The presence of prostatitis may always be confirmed by a digital examination and will be suggested by various suspicious phenomena, such as frequent micturition at night, a diminishing energy of the sexual functions, a complicating sciatica, or the presence of various nervous or mental phenomena—various obsessions or inability to concentrate the mind—sexual neurasthenia. Mental disturbances have been found present in fully twenty-five per cent. of the cases that have come under my observation and have often led to the diagnosis. There probably is no more common cause of neurasthenia in the male than this condition and it is so important that the attention of the nerologist should be awakened at once to the possibility of such a cause and the case promptly referred to the urologist.

In the treatment of uncomplicated cases, it is remarkable how promptly the nervous phenomena are relieved. This should lead therefore to the digital examination in all cases of neurasthenia in the male, and if an enlarged or sensitive prostate is found the indicated treatment should be promptly administered. A condition which may cause an added complication of dysuria is the presence of a projecting enlargement of the verumontanum which is often not entirely relieved by the static currents. This condition is encountered in a small percentage of cases and is not relieved by the static current but requires special attention of a surgical nature.

The intelligent employment of the method described should effectively cure all uncomplicated cases of prostatic inflammation, and offers a possibility equal if not greater than any other measure in vogue of curing prostatitis in the early or acute stage. It forestalls the necessity of a surgical procedure in many cases as well as leaving the patient in a normal physical and mental condition. We realize that this statement will seem sweeping to those who have been familiar with other methods, but the statement is based upon results obtained in the management of upward of three hundred cases, more than two hundred and fifty of whom have remained cured for varying periods of time up to twelve years, and is verified by all who intelligently employ the method. This method was discovered by the writer and first published by him in 1903 and has been employed by a large number of clinicians with the same success as that obtained by the writer since its discovery.

Epididymitis was first treated, by the method to be described, by the writer in 1904 when a servant who had been suffering from an attack of acute epididymitis with an extensive enlargement and great tenderness was promptly relieved. For two days he had been kept in bed with an ice bag applied to the parts. Obtaining no relief it occurred to me that the application of the same method as to infiltration elsewhere might be effective in the treatment of epididymitis. I therefore applied the static wave current, beginning with an electrode applied to the upper end of the gland, and softening the areas progressively from above down. In three-quarters of an hour the swollen gland was reduced fully one-third in size and the tension and tenderness were relieved. Following two more applications the parts were reduced to normal and no further trouble occurred. This method has been uniformly successful in the hands of everyone who has employed it, usually completing the cure in three or four days. We employ a cup-shaped metal electrode, connected with the machine by a metal cord, and held in position by the patient with a towel. The treatment is continued for fifteen or twenty minutes, once daily, until the infiltration is resolved. It rarely requires more than two or three administrations to effect a complete cure.

In specific vesiculitis the method to be described probably comes as near, or possibly nearer than any other method to rendering the parts free from infection. This is well demonstrated by the successful treatment of chronic gonorrheal arthritis in which the persistence of the arthritis is undoubtedly due to a toxic poisoning from the infected vesicles as a source. Following Dr. Fuller's description of the successful treatment of gonorrheal arthritis by curetting the vesicles, the method to be described was suggested and instituted by the writer and has been regularly successful in the hands of all who have employed it intelligently. This was recently demonstrated by me in the genitourinary clinic at Johns Hopkins Hospital.

It is customary in these cases to use first a glass vacuum electrode. It is immaterial whether it is made a localizing insulated electrode or a straight uninsulated rectal electrode, if as much current is employed as can be withstood with the heat produced. The application is directed to the vesicles for ten or fifteen minutes, preferably from a coil or transformer, and then followed by the use of a metal electrode, with the static wave current, the same as used for the treatment of prostatitis. The electrode is carried well up against the vesicles, and the application is continued for 15 minutes daily until the vesicles are cleansed of infection.

In 1902 it was discovered by Dr. Herman Grad that the vesicles though containing a waxy content could be emptied by this method, and when Fuller established the fact that the arthritis was of toxic origin from infected vesicles the writer immediately put this method into use, and, as stated, it has always proved successful in uncomplicated cases of gonorrheal arthritis.

The fact that it relieved gonorrheal arthritis immediately suggested the employment of the method in the same manner for the treatment of vesiculitis with the presence of shreds in the urine; and I know of no other method in vogue to-day which offers so much for freeing the genital tract from gonococci as the employment of the static current, expelling as it does the content through the natural channels, and at the same time seeming to destroy the virility of the germs present.

If I have made clear the rationale of the methods described I will have proved that the process is a rational one, and while the relative degree of success in the percentage of cases that come under observation may be questioned, it remains for the genitourinary specialist to confirm or disprove the writer's claims as set forth.

2020 Broadway.

REMARKS ON METHODS FOR THE PREVENTION OF INSANITY.*

By W. M. KENNA, M.D.,

CENTRAL VALLEY, N. Y.

ASSISTANT PHYSICIAN, DR. CARLOS MACDONALD'S HOUSE; FORMERLY ASSISTANT PHYSICIAN, CONNECTICUT HOSPITAL FOR INSANE, MIDDLETOWN, CONN.

THE writer intends these remarks as a résumé rather than as an offering of anything with which you are not entirely familiar. He merely feels that discussion in medical societies of the subject at hand will be of aid to all of us who are so painfully but hopefully groping in the dark for a solution of the insanity problem, and awaiting the light which may lead us on our way with confidence and with something of precision.

The hard and fast, and generally accepted, dividing line which has always existed between sanity and insanity is rapidly disappearing; and we are coming to appreciate that instead of there being a chasm which separates the two states they are in reality almost intimately fused; that, after all, there is not the essential difference between the two conditions which it has been customary to believe there was.

One who is connected with a hospital for the insane is more especially in a position to observe the changing viewpoint of the laity in this regard, coming, as he does, into daily contact with the relatives and friends of the patients who have been committed as insane. It may seem trite to refer to this fact or to the subject of these remarks before the members of this society, but in any event, the matter would seem worthy of emphasis. For if anything can be done to break down the well-known prejudice existing against the disease of insanity surely the end justifies the means, and it is a hopeful sign that such prejudice is being rapidly dissipated. Not a little of the credit for this is due to the attitude of the general practitioners of to-day, who apparently are taking more of an interest in the subject of insanity and in the welfare of the insane than those of past generations. And men in other professions are following the lead of physicians and are showing an interest in a subject long ignored. That there has been and that there still is a stigma attached to insanity everyone must frankly admit.

As an example of the broader view which is coming to be held, however, reference may be made to the attitude many judges of courts are taking in their disposal of cases which are brought before them—of people who are suffering from the excessive use of alcohol. Much more frequently than formerly the sufferers from alcoholic poisoning are being sent to hospitals for the insane as the recognition is becoming more prevalent that alcoholism is a disease rather than a crime. I mention this as bearing on the increasing tendency to adopt means for the prevention or for the early recognition of insanity, and as demonstrating a more intimate appreciation of abnormal mental states.

The ways and means of solving the problem are for the most part only in the process of crystallization; but that they are being launched here and there is comforting and refreshing. And it is primarily the prevention of insanity toward which we should bend our efforts. Asylum physicians more acutely than others realize the futility of hoping for a cure in many of the cases which are committed to their care. More perhaps is expected of these members of the profession than is really fair. For be it known, many cases even on admission to the hospitals for the insane are already really in a state of chronicity, judging from a careful scrutiny of the anamneses of the patients. The asylum physician, one might say, is in much the same predicament that confronted the practitioner of some years ago, when the inflamed appendix was overlooked and his conscientious endeavors were directed to the relief of the ensuing general peritonitis.

It would seem to the writer that just as the fact that the early symptoms of appendicitis are now so quickly recognized and that this results in the prevention of physical catastrophes and very often death, just so, in the future perhaps, will there be fewer relics of once undeteriorated brains because of the acumen of physicians in recognizing the earliest symptoms of an impending psychosis and in instituting protective measures in time to check its initiation.

For it would appear there are few cases of sudden insanity. The histories of patients committed to insane hospitals in many cases show prodromes of momentous import which have been overlooked or ignored until the final crash comes and as a *dernier ressort* or as a necessity the unfortunate ones are haled into court and committed to hospital care. Thus the increasing attention which is being paid to the subject not only by physicians generally but by the laity as well, bids fair to accomplish much in the practical prevention of a large number of cases of alienation.

As causative factors alcohol and syphilis of course stand out boldly and present their numerous cohorts. And so if we were smug and narrow we might complacently shrug our shoulders and dismiss the matter with a word: "Eliminate alcohol and syphilis and we would have no alcoholic or syphilitic psychoses." But we know perfectly well (while we do not quite understand why) that all syphilitics do not develop paresis; nor do all people who over-indulge in alcohol show subsequent deviations from an accepted mental norm.

Now the writer holds no brief for the ecstasies of a syphilitic infection nor for the dreamy abnormalities of the alcoholic; he wishes rather to plead for the innocent sufferers of the dementia precox, involution, and senile groups, many of whom (women for instance) have never looked upon the wine that is red and whom the gracile spirochete has never dared to approach.

It would appear that it is for all of us physicians to look upon insanity not as a thing apart; not as though a division wall were strongly erected between the two states of sanity and insanity; but with the earnest expectancy, watchful though sorrowful, that certain individuals under our observation are, if not properly guided, foreordained to step out from the realm of accepted sanity into the abyss of recognized *insanity*. May not the cogent personality, active and potential, which every doctor possesses prevent, metaphorically speaking, the acute appendicitis from becoming a general peritonitis?

It seems certain that the psychological clinics which are being instituted in various parts of the country will in time exert a powerful preventive influence upon the development of insanity. Our own Connecticut Mental Hygiene Society is doing commendable work in the line of prevention and its

*Read at a meeting of the Central Medical Society.

efforts have already succeeded in stimulating an interest which is national in its scope. We are coming to grasp with greater sureness the necessity and importance of studying the trends of the brain, not in maturity when perhaps it is too late, but in childhood and adolescence before the abnormal proclivities of cerebral activities have become accustomed to follow the beaten paths which lead to mental obliquity.

The Binet-Simon test, for example, which has lately come so prominently to the fore, has opened our eyes somewhat and has ruffled our calm contentment. One swallow does not make a spring, but a moving straw indicates the direction of the wind; and we read in the report of the Boston Psychopathic Outpatient Department that as a result of the examination of children between 10 and 20 years of age taken to the clinic, in 71 per cent. of the cases adolescence had a distinct bearing upon the reasons for their being presented, and that 39 per cent. were after careful survey, thought to be normal physically; 75 per cent. were found to be defective or retarded.

So it is obvious that one of the possibilities of prevention rests with us in the more intimate study of the mental trends of our children. The delicate adjustment of the splint to prevent the otherwise possible resultant deformity should apply mentally as well as physically.

Fitzgerald of California recalling that communities generally are blessed with hospitals nowadays, maintains that each hospital should concern itself with the mental health of its own particular neighborhood, showing an adoption of the unit organization idea, and makes the suggestion that since in cases of infectious diseases immediate means are taken against their extension, similar methods should be instituted, when an individual case of insanity crops out, as a protection to the others of the family from the dread condition. He also recommends public lectures on methods of prevention, the explanation to families of the factors involved in any particular case of insanity arising, and emphasizes the obligation of physicians to place due but not hysterical accentuation upon the dangers of alcohol, syphilis, and heredity as etiological factors.

The so-called social service element as part of our armamentarium is to be considered. This perhaps will always meet with the cool reception that a seeming violation of the old adage "one's home is one's castle" invites; but that its possibilities are great, if tact is used, cannot be denied, and its main benefits may come, not alone in the prevention of initial attacks, but also in its help to the convalescing or recovered patient as a means of warding off a relapse or preventing a fresh invasion.

As to eugenics, who shall decide? Who shall have the insufferable effrontery to eliminate ruthlessly the human emotional elements which are so potent and so common in the natural selection of mating? Education and common sense must be the bulwarks of protection in this respect and eugenics may find its endeavors limited to awakening the public to the dangers of ill-mating and with the knowledge thus gleaned, allowing the latter to guide itself accordingly. And shall we sterilize the male and be audacious enough to take away from any one his possible ability to procreate the species? The solution of this problem is still subjudice and is most certainly beyond the writer's ken.

Is it not environment which oftentimes presents itself as the potent etiological factor in the causation of insanity? And cannot physicians with the aid of their keen insight into conditions of a pathological nature, do much to neutralize many irritating and exasperating influences under which the possible future inmate of a hospital for the insane may happen to be placed?

With all the crowning and intrinsic beauties of the home and with all its sacredness, is it not true that this oftentimes, unfortunately, carries with it some of the basic elements of the etiology of alienation? I refer to the worries, the fears, the irritations which we know exist all about us; the financial distress here, the religious doubt there; and again, for example, the phantasms of jealousy; the morbid obsessions—all of which form sleeping neurotic coals ready on the instant to be fanned into the flame of a psychosis.

Dr. Osler in an address before the Henry Phipps Psychiatric Clinic suggests that such headings as the following may shortly be found on our diagnostic slips: "Mr. J. A.—A tendency to irritability of temper." "Mrs. R.—Too much given to introspection." "Miss B.—Over-anxious about her soul." "Master G.—Worried by a neurasthenic mother."

Again, if we accept the teaching of Freud and other psychanalysts, that not only psychoses but almost everything else in the world has a sexual basis, shall we not perforce be obliged to attack the question of sex and sexual relations with greater interest and avidity and moreover, freedom, than we have heretofore shown?

It may be that Harvey Cushing in his brilliant investigations of the ductless glands is arriving at the truth concerning the real causes of some insanities. He is already making inquiries as to the relation between the abnormal secretory action of these glands and certain mental obliquities. But since he admits that individuals vary greatly in the exhibition of the secretory response of these glands to emotional strain, is he not at one with the distinguished physician above quoted who while speaking to the students of Yale University some time ago on the subject of mental health, warned them of the futility and inadvisability of worrying about events which had already happened, or of anticipating those to come. He summed up his ideas in the following concise and wise though perhaps somewhat iconoclastic aphorism: "Forget yesterday; forget to-morrow; think of to-day!"

QUININE AFTER RECTAL OPERATIONS.

WITH NEW TECHNIQUE.

By EDMOND BONNOT, A.M., M.S., M.D.,

ST. LOUIS.

DURING the past eighteen months I have used quinine after all laparotomies,[1-2] but it is only since recently that I have used quinine after all operations where ether was administered, and after all cases in which local anesthetics were used where the operation was of any consequence. It is only during the last five months that I have used it following rectal operations. Since then I have used it in sixteen cases, ten hemorrhoidectomies, four operations for rectal fistulæ, and two cases of fissure in ano. This has proven even more satisfactory to the patient than in other operations.

In hemorrhoidectomies, after thoroughly dilating the sphincter muscles, I use the clamp cautery

method, previously separating the skin with scissors, so as to include only the mucous membrane in the clamp, and use the ordinary soldering iron to a dull red heat for cautery. In fissure and fistula I use the ordinary methods of cutting, curetting, and cautery, as the case may require. After the operation is completed I insert a soft rubber tube 6 in. long and ¼ in. internal diameter into the rectum, with a safety pin to the outer end to prevent slipping in. After the patient is returned to bed he is given 10 grains of quinine muriate dissolved in 2 ounces of water at 100° Fahr. through the tube, which is clamped for one hour to prevent the fluid from escaping. This is repeated once after six hours and the tube is then withdrawn. The next day the patient is given 1½ ounce of castor oil.

The result is that the patient has no pain or tenesmus in the least, not even when the bowels move. The gas escapes freely, there is a free bowel action the second day, and every day following. If after three or four days there is some soreness or swelling the patient is given a salve to apply to anus as follows:

℞ Extract of Opium, ʒi.
Extract of Belladonna, ʒss.
Cocaine muriate, gr. x.
Ichthyol, ʒi.
Petrolatum, q.s., ad, ℥i.
Sig.: Apply when desired.

The patient never requires morphine. Of the sixteen cases none had any more than a slight soreness in the rectum. The patients are able to leave the hospital in from four to six days. The quinine has a distinct local anesthetic effect that lasts until the condition is healed. The thirst, nausea, and vomiting are very favorably influenced as in other operations. By reason of the ichthyol in the salve and the quinine, which are antiseptics, healing takes place more rapidly.

PICRIC ACID AND BENZIDIN STAIN; A TRANSITIONAL CELL IN GENERAL PARALYSIS.

By B. Lemchen, M.D.,
Dunning, Ill.
Chicago State Hospital.

On September 11 I described in the Medical Record a new stain for cerebrospinal fluid. Now I have modified the stain, because the new one brings the cells out clearer. The way I make this stain is as follows:

I dissolve 1 per cent. benzidin in glacial acetic acid. I add an equal amount of saturated solution of picric acid in water, and filter. The reason I filter is because some of the picric acid is precipitated. This I call Solution No. 1. Solution No. 2 is hydrogen peroxide, and the rest is the same as the original benzidin test which I reported on September 11; that is, when I am ready to stain the cells I place some of solution No. 1 with an equal amount of solution No. 2 in a small test tube, mixing them together. Then I take a white cell pipet, draw the staining fluid to the .5 mark, the spinal fluid to the 11. mark, mixing them well together; then I place on the counting chamber and count the cells. The cells, with a few exceptions, which I will explain later, take the same stain as with the original benzidin test, except that some of the cells which are not stained with the benzidin are stained yellow with the picric acid and so are plainer. In other words, most of the red cells that are not dissolved stain blue, while some of them stain a brownish yellow to a dark brown. The polymorphous leucocytes are stained yellow, with the exception of the granules in the nucleus which are stained dark blue. The lymphocytes stain yellow with blue granules and a blue ring; the plasma cells are stained yellow with the blue rings surrounding.

I have found a cell which is constantly present in general paralysis of the insane; it is a cell a little larger than the red blood cell; the protoplasm is stained a light blue; the nucleus, which is always on the periphery, is stained a dark blue, almost green. This cell apparently has the same origin as the red blood cell, because it takes the same stain, and I consider it to be a transitional cell of the plasma cell for the reason that both its protoplasm and its nucleus are more or less homogeneous, there are no granules that I can see, and the nucleus is excentric.

In a careful study of all the cells it seems to me that the red cells apparently have different origin, the reason being that not all of the cells take the blue stain. It has been thought for quite a while, but has never been proven, that the red cells have their origin in the hemolymph glands as well as in the bone marrow, and also in the spleen; this has been denied by others, but I think this statement is correct. There is another thing to be deduced from this: Since we find transitional cells which must have their origin at the same place as the red blood cells, therefore, the plasma cells may have their origin in the blood-forming organs, and as such the function of the red blood cells is not only to carry oxygen to the different tissues of the body but in certain conditions they may also produce cells that are defensive in character. This might account for some of the good results that we are getting in general paralysis from tonics, including iron and arsenic, and hygienic treatment; and it is known that these measures stimulate the blood-producing organs to better activity.

In conclusion I would like to state, after my investigation, that the acid picric benzidin stain is a reliable one for cells in the cerebrospinal fluid, and the red blood cells apparently have more than one origin. The plasma cells in all probability have their origin in the blood-producing organs. There is a cell that has the appearance of the plasma cell and takes the same stain as the ordinary red blood cell, which I have constantly found in general paralysis of the insane; this appears to me to be a transitional cell, and for the sake of a better classification I will call it the transitional cell of Lemchen.

Immunity Against Tuberculosis Through Drinking Milk.—Moss in experiments on cows concludes that a relative degree of immunity against tuberculosis may be conferred upon calves by feeding the milk of vaccinated cows. "Further experiments are necessary to determine if human beings may be similarly influenced."—*Johns Hopkins Hospital Bulletin.*

ACHALASIA OF THE CARDIA.

THE coinage of a new word in medical nomenclature is fully justified when the new term connotes a condition that is not exactly described by any existing word, and that would otherwise require a cumbrous phrase for the conveyance of its meaning. "Achalasia" is literally "absence of relaxation" and when applied to the cardiac orifice of the stomach signifies a condition that has for a long time been denominated by the term cardiospasm, or the so-called idiopathic dilatation of the esophagus. Arthur F. Hertz (*Quarterly Journal of Medicine*, July, 1915) points out that the dilatation of the esophagus without organic constriction, which was first described by Hannay in 1833, was attributed by Mikulicz in 1882 to a spasm of the cardia, and within recent years this condition has been designated by the term "cardiospasm." But Hertz believes that this conception is incorrect, advancing abundant evidence to prove that the dilatation and hypertrophy of the esophagus are due to the absence of the normal relaxation of the cardia. For the coinage of the word "achalasia" Hertz acknowledges indebtedness to Sir Cooper Perry.

In none of the cases of so-called cardiospasm in which the symptoms had existed for many years before death has there been observed an hypertrophy of the cardiac sphincter analogous to the greatly thickened pylorus in the hypertrophic pyloric stenosis of infants. This fact tends to support the view advanced independently by Rolleston and Hertz that dilatation of the esophagus is the result of a failure in the coordinating mechanism by which the cardiac sphincter is relaxed during swallowing. *X*-ray observations and experiments on animals show that the cardia relaxes when each peristaltic wave, passing down the esophagus in the act of swallowing, reaches its lowermost end. A failure in this relaxation results in the stagnation of food in the esophagus, which dilates as more and more collects in it. The resulting increased peristalsis accounts for the marked hypertrophy of the dilated esophagus. Hertz has found that in spite of the fact that strong peristaltic waves are unable to overcome the obstruction, the weight of an India-rubber tube filled with mercury is sufficient to cause it to drop without the slightest difficulty through the cardia into the stomach. The tube can also be withdrawn with greatest ease. Neither of these phenomena would be possible if the obstruction were due to spasm. Achalasia of the cardia may, however, be complicated with cardiospasm, in which instance there is some resistance to the passage of the weighted tube.

In the majority of cases of achalasia of the cardia there is discoverable no obvious cause. In a few instances the failure of relaxation is the result of reflex inhibition from an ulcer or carcinoma of the stomach; from inflammation or ulceration of the lower end of the esophagus; from extreme dilatation of the right auricle; or from a degenerative lesion of the vagus nerve. The condition may begin at any age and generally develops gradually, the attacks at first occurring at intervals of a few days, weeks, or months, until finally the condition is permanent. The attacks often begin in the morning, when the patient experiences difficulty in swallowing saliva. Upon ingesting food the patient feels as if this "sticks" and often recognizes that the obstruction is beneath the lower end of the sternum, but sometimes the sensation is felt in the upper part or middle of the chest. Sometimes actual pain is felt. Salivation is present in almost every case. As a rule the patient is relieved by vomiting almost all he has eaten within a few minutes after finishing a meal. Generally this is done quite easily, but occasionally the vomiting reflex is initiated by the patient tickling his throat. Liquids are swallowed more easily than solids. A small portion of the food passes through the cardia in a steady stream, but as soon as the weight of the column falls below a certain point or the individual lies down the pressure becomes insufficient and the flow ceases. The esophagoscope shows that the cardiac orifice is completely closed. The general health remains good in contrast to what occurs in malignant obstruction of the esophagus. After a certain amount of loss of weight a stage of equilibrium is reached.

In the diagnosis of achalasia of the cardia, which is confirmed most easily with the aid of the *x*-rays after a meal of porridge mixed with milk and barium sulphate, one must exclude the possibility of cancer and of non-malignant stricture of the esophagus. Achalasia is distinguished by the intermittent character of the early attacks, the absence of constitutional symptoms, and the comparatively early age of onset; and, when diagnosis is not made early in the disease, by the long duration of the illness. The only conclusive evidence is said to be the great ease with which a weighted tube passes through the cardia in achalasia in contrast to the complete obstruction offered by a growth.

The treatment consists in the use of a mercury-weighted tube of 20 to 24 gauge, which is allowed to drop through the cardia and one inch beyond it. It is left in position for a few minutes at first, but later it can be withdrawn directly after it has entered the stomach. The tube is passed immediately before meals, at first before every meal, then once a day, and later at less frequent intervals. This treatment is said to be simple and effective.

Hertz believes that the condition called water-brash, the "vomissement pituiteux" of the French, and certain allied phenomena can be most satisfactorily explained as due to a special form of achalasia of the cardia.

THE REHABILITATION OF DRUG THERAPY.

In the progress of medicine quite as much as in the progress of social or political reforms we have become accustomed to an overswinging of the pendulum on the part of those who advocate something new. In fact it is generally accepted that there must be this overswinging of the pendulum to attract attention to the innovation. It is not so very long ago that everything was swinging over in favor of therapeutic nihilism, in so far as drug therapy is concerned.

The success of diphtheria antitoxin prepared the imagination for belief in a new system of serotherapy for the infectious diseases, and while it did seem for a time that everything was swinging that way, it must not be forgotten that there were workers at the old problem, started by Lister, of trying to find a chemical compound that would destroy infective germs and yet not injure the tissues. In 1902 Laveran and Mesnil first demonstrated the trypanocidal action of arsenic in experiments on animals. In 1905 Thomas published his work on atoxyl; Uhlenmuth soon extended the field of specific arsenic therapy to spirochetal infections; and then Bertheim and Ehrlich opened the way for greater exactness in specific therapy by determining the chemical constituents of atoxyl. Salvarsan soon followed, and later, neosalvarsan—but the old problem is still before us, as shown by Brown (*Johns Hopkins Hospital Bulletin*, October, 1915), who reports on the lesions caused in arsenotherapy, and the difficulties met in prosecuting research along this line at the Rockefeller Institute. It seems that at times unexpected results are brought about, either by peculiar selective effects of the arsenic or by the production of potent organic poisons. We have not as yet a chemical compound that we can inject into the circulation, which will not do more or less damage to the vascular system. We have made great progress in arsenotherapy since the days when Livingstone was in "darkest Africa" and used arsenic in the treatment of "fly-bite," but we are not yet at the end of our work in chemotherapy; and, on the other hand, in chemotherapy no less than in serum therapy, there are not grounds for thinking that all progress in the future therapy of infectious diseases is going to be in its direction.

A line of work just reported by Moore on the chemoserotherapy of experimental pneumococcal infection suggests a possible way for further progress without any overswinging of the pendulum. Moore by injecting a hydroquinine derivative and antipneumococcus serum into mice infected with pneumococcus found that the efficacy of the serum was increased at least fifty times; that the effect was many times greater than a simple summation of the effects of the drug and the serum. (*Journal of Experimental Medicine*, October 1, 1915.) This word, drug, is rarely used in the ultrascientific literature these days, but nevertheless much of the research has to do with drugs. This fashion has so influenced us that we are really not apt to think, for instance, of the Ehrlich-Hata preparation as a drug. It is in researches such as these that we can see that therapeutic nihilism is going to belong to the past.

In the field of specific therapy, quinine long ago fully justified drug-therapy; thyroid has fully justified organotherapy; diphtheria antitoxin has fully justified serumtherapy; all of these—to use an old-fashioned word—remedies, are biological products. If we may judge of the future by these past achievements, we should expect continued progress along any line in therapy which does not forget that the life processes of a plant or an animal excel in the production of delicate chemical compounds for specific purposes. The secret is to find the products or to influence their natural production, so that they may be turned to our purpose.

THE DETERMINATION OF PLASMA AND BLOOD VOLUME.

With the introduction of the numerous methods for the quantitative determination of various substances in the blood there has come the need for some reliable method for the determination of the amount of blood. It is true that this has been done to a certain extent upon animals in the laboratory, but the results are not translatable to man to any exact degree. The methods hitherto used upon man have been only approximations and for the most part unsatisfactory. Recently there has been introduced by Keith, Rowntree, and Geraghty (*Archives of Internal Medicine*, 1915, xvi, 547) a method based on the introduction into the circulation of a non-toxic, slowly absorbable dye which remains in the plasma long enough for thorough mixing. The concentration of the dye in the plasma is then determined colorimetrically by comparison with a standard mixture of dye and serum. The relation between the plasma and the whole blood is determined by means of the hematocrit. The dye selected is known as vital red and is disodium disulphonaphthol azotetramethyl triphenyl methane. It proved non-toxic in doses of 3 mg. per kilo, which was the amount used. In dogs, traces appear in the urine and in the lymphatic duct at the end of ten minutes and in man it is to be found in the urine for three or four days following its injection.

In carrying out the estimation, the calculated amount is injected into an arm vein, and three minutes later blood is withdrawn from a vein in the other arm for the estimation. Comparison is then made with a solution of the dye in serum which has been removed from the patient before the injection of the dye. Controls were made by repeated estimations on the same patient, by the use of different doses of the dye and by estimation of the blood volume before and after venesection and infusion, and all tended to show the accuracy of the method. In applying the method to normal men the authors found the plasma volume to vary from 1/17 to 1 23 the body weight, the average being 1 19.4. The whole blood on a gravimetric basis varied from 1 13 to 1/10.5 of the body weight with an average of 1 11.5. These variations are very much less than those obtained by the use of methods hitherto available. The average, however,

is not far from the figures usually accepted as normal. In a somewhat limited investigation of pathological conditions they determined an increase in the blood volume in pregnancy, some cases of anemia, and in one case of polycythemia. A small volume was found in obesity and in many cases of marked hypertension. The method is a comparatively simple one and is apparently accurate. It should prove of great value as an adjunct to the present methods of blood analysis, which give merely percentage figures and therefore possess only a relative value.

A German "Soft Drink."

Most "soft drinks" are regarded as crude jumbles, unscientific in conception, with a tendency to cause gastric disturbance, without delicacy or flavor, and inferior to slightly alcoholized beverages, in that the latter have stomachic properties, are more palatable and standardizable, and do not pall upon the consumer. The fact that cider, despite its alcohol content, can be used temperately by thousands who could not drink other alcoholized beverages without habit forming, suggests that it possesses something besides alcohol to render it acceptable to the drinker. Of course, there have been cider drunkards and communities which have abused cider, but they are in the minority. In a note to the *Münchener medizinishe Wochenschrift* for August 17, Professor Ziemann gives the recipe for what he calls an artificial alcohol-free cider which he says is both sweet and sour and aerated and has a delicate flavor. This is as follows: Fifty grams of ash leaves are mixed with four liters of water, brought to a boil and allowed to draw for 2 hours in a closed vessel. The infusion is now placed in a cask and the following are added: A hundred grams of tartaric acid dissolved in one liter of warm water; one liter of cold infusion (2 hours) of chicory (100 grams); 80 grams fresh baker's yeast dissolved in ¾ liter of cold water by stirring; five kilos crystallized sugar dissolved in warm water. Water is now added to make 100 kilos. The cask, placed in the cellar, is allowed to remain untouched, for from 12 to 18 days, according to the temperature, the bung being loosely inserted. The pseudocider is now ready for bottling. Corks had best be wired and blank space left in the bottles. We fear the assumption of Professor Ziemann that this is a "soft drink"—that is to say, free from alcohol—would not be accepted in any prohibition State or by any first year student of chemistry.

The Problem of Immunity.

In succession ten or more theories of immunity have come and gone, each having been found fallacious. The inadequacy of Ehrlich's widely accepted side-chain theory has recently been pointed out by Coca (*Journal of Infectious Diseases*, September, 1915) in the case of natural immunity. He states that Ehrlich's theory is applicable in the case of the scorpion being immune to its own venom, or of the hedgehog to the viper's venom, for in these cases the blood contains some antitoxin property, but that in the case of the remarkable natural immunity of the fowl to tetanus toxin, the theory is inadequate because the blood of the fowl, although the fowl is immune, is not antitoxic. Inasmuch as this natural immunity may be overcome by temperature, Coca suggests that it may after all depend on the physical condition of the protective tissue or sensitive cells. In other words, it is a problem in physical chemistry.

News of the Week.

New York City Death Rate.—During the week ending October 23 there were in New York City 1,296 deaths with a rate of 11.64 as compared with 1,216 deaths and a rate of 11.36 for the corresponding week of 1914.

Chicago Death Rate.—During the week ending October 23 the total number of deaths reported in Chicago was 533, which was 50 less than during the preceding week of this year and 4 less than during the same week of last year. The annual death rate for the week was 11.4 per 1,000 of population, as compared with 12.4 for the preceding week, and 11.7 for the corresponding week of 1914.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, M.D., treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the following contributions received during the week ending October 30, 1915:

Dr. J. Shelton Horsley, Richmond, Va. (second contribution)		$5.00
Previously reported receipts		7,866.84
Total receipts		$7,871.84
Previously reported disbursements.		
1,625 standard boxes of food at $2.20	$3,575.00	
1,274 standard boxes of food at $2.30	2,930.20	
353 standard boxes of food at $2.28	804.84	
Total disbursements		7,310.04
Balance		$561.80

War Contributions to Red Cross.—At the annual meeting of the New York County Chapter of the American Red Cross, held at the Waldorf-Astoria on October 28, it was announced that the war contributions to the American Red Cross Society had amounted to $1,600,000, since the relief work was started in September, 1914. All the supplies sent to Europe have been handled and shipped from New York. Dr. Richard P. Strong of Harvard University, who was at the head of the American Sanitary Commission which was sent to free Serbia from typhus, told the story of the cleaning up of that country. Not only was typhus fought, but it was found necessary to vaccinate the people against cholera also. The sanitary work was internationalized, the French, Russians, and British taking charge of seven of the fourteen districts into which Serbia was divided, while the Americans had charge of the remaining seven.

Americans Care for Russians.—A recent report from Rome states that a contingent of the American Red Cross from Serbia passed through Italy on October 29, on the way to Germany to aid in the care of Russian prisoners in that country.

Temperance in England.—The anti-treating order in England is said to be proving very useful. The Coroner of Southwark at an inquest recently stated that the order had done more to stop drunkenness than anything else in his experience that the Government had done.

Cavell Memorial.—The proposed memorial to Miss Edith Cavell, the English nurse in Belgium who was executed as a spy by the Germans recently, may take the form of a branch of the London Hospital to be called by her name. The

suggestion has been taken up by the London press and the execution of the plan seems almost certain.

Women Physicians in London.—The status of the woman physician in England has changed greatly since the beginning of the war. Positions on hospital staffs which have heretofore been held exclusively by men, are now offered to women, and the demand is considerably in excess of the supply. Before the war, for instance, an infirmary physician in the Whitechapel district, always a man, received $500 a year and emoluments, while now the infirmary is advertising for a woman physician and offering a salary of $1,000 a year and emoluments. It is reported that the Woman's Medical School of England has trained 600 women physicians and that 220 students are registered there.

British Army Sanitation.—Sir J. Crichton Browne, presiding at a conference of the Sanitary Inspectors' Association in London recently, stated that in the present war, with a larger army than England had ever before had in the field, the mortality from disease had been lower than in times of peace. Although nearly 500,000 men have been reported killed, wounded, or missing so far, the number would have risen to a million if the rate of sickness had been the same as it was in South Africa. But for the enormous strides made in sanitation, especially in the last ten years, he said, the British Army in France and on the Mediterranean would be in a perilous plight.

Traveling Hospital.—Dr. Alexis Carrel, who has been for some time in charge of a hospital at Compiegne, will, it is announced from Paris, devote part of his time to operating in a traveling hospital which will be composed of five automobile trucks. Two of these will carry a portable operating room, another a sterilizing plant, a fourth an electrical generating plant, and the fifth an *x*-ray room. The traveling hospital will shortly be sent to the front, where it will be thoroughly tried out, retreating only during bombardments. Dr. Carrel will still retain supervision of the Compiegne Hospital.

Hospital Staffs Safe.—The Serbian Legation in London stated on October 28 that the staffs of the British hospitals in Serbia were all safe. The doctors and nurses who had been at Uskub were reported to have reached Monastir in safety.

Race Degeneracy.—Out of 600 applicants for the United States Navy examined recently in Boston, but thirty were accepted, the remainder being rejected as physically below the normal or mentally or morally unfitted. From this, Rear Admiral Albert Ross, U. S. N., deduces that we must make our rapidly degenerating citizenry into men before we can make sailors or soldiers.

Premium on Children.—In Saskatchewan, Canada, there has recently been adopted a law providing that every time a mother gives birth to a child the Province shall pay her $25. The medical attendant is also paid a fee of $15 by the Government The doctrines of Malthus evidently strike no terror into the hearts of the lawmakers of Saskatchewan.

To Enforce Sterilization.—The Wisconsin sterilization law, passed by the Legislature of 1913, will, it is reported, be put into actual operation some time in November, when twenty-four inmates of the home for feeble-minded in Chippewa Falls will be submitted to surgical treatment for this purpose.

Scarlet Fever Epidemic.—Infected milk from a dairy in West Town, N. Y., is said to have been responsible for an epidemic of scarlet fever in several towns in Bergen County, N. J. Nearly forty cases, with one death, were reported in October.

War on Nostrums.—The Board of Health of New York City, at a meeting held last week, passed an amendment strengthening the ordinance which will become effective on January 1, 1916, requiring that any patent medicine sold in New York City must have its formula registered with the Department of Health. As originally enacted, the vital paragraph of the section read: "The names of the ingredients of every such medicine shall be registered in the Department of Health in such manner as the regulations of the Board of Health may prescribe." But as it was felt that this was not entirely clear the Board amended it to read: "The names of all ingredients to which the therapeutic effects claimed are attributed and the names of all other ingredients except such as are physiologically inactive shall be registered in the Department of Health in such manner as the regulations of the Board of Health may prescribe." The information obtained through such registration will be held in strict confidence by the Department. The Board announces its intention to enforce the ordinance and is prepared to fight those manufacturers of patent medicines who show an unwillingness to comply with its terms.

Dr. Goldwater Leaves the Health Department.—The resignation of Dr. S. S. Goldwater as Commissioner of Health of New York City, after being in the hands of Mayor Mitchel since last July, finally, on Dr. Goldwater's insistence, became effective on November 1, the Mayor meeting the situation by appointing Dr. Haven Emerson, Sanitary Superintendent, to fill the place temporarily. Dr. Goldwater will return to his work as superintendent of Mt. Sinai Hospital, a post from which he was given leave of absence in order that he might enter the service of the city. Chief among his activities as Commissioner have been his endeavor to regulate the transit difficulties, the enforcement of rules regarding the muzzling of dogs on the city streets, the abolition of disinfection following cases of certain infectious diseases, the wholesale physical examination of occupational workers, and the sanitary clean-up of Coney Island. Dr. Emerson is known to have been in complete accord with Dr. Goldwater's policies, and it is not unlikely and is greatly to be desired that his appointment may be made permanent. As sanitary superintendent he has been especially active in the campaign against the drug evils.

Fresh Air Cars.—For the benefit of those who believe in fresh air, it is proposed to operate on the elevated railway in Chicago, during the winter, windowless and unheated cars. One such coach will be attached to each train and will be marked "Fresh Air Car."

Willard Parker Hospital.—A new building to house the medical staff and to serve as a Nurses' Home is now under construction at the Willard Parker Hospital, New York. Quarters will be provided for thirty-five doctors and 115 nurses. The building will include a swimming pool and a gymnasium, and special rooms for sewing, etc., will be fitted up for the nurses.

Police Psychology Squad.—The police of New York City are to be given instruction in psychology, the course beginning on October 30, with a lecture

at Police Headquarters on "Mental and Moral Defectives," by Dr. Louis E. Bisch, who with Professor Thorndyke of the Department of Psychology of Columbia University, is giving his services. By these lectures the Police Commissioner optimistically believes "a mental standard of recognition will be inculcated, so that officers on duty may be immediately aware of a mental or moral defective when confronted by one." Dr. Bisch and Professor Thorndyke will also act as consultants to the department, to the end that those who require special attention may be examined and if necessary committed to a hospital or sanatorium instead of to a penal institution.

Favor National Board of Medical Examiners.—At the forty-first annual convention of the Mississippi Valley Medical Association, held recently in Lexington, Ky., the following resolution, offered by Dr. H. H. Grant, was unanimously adopted: "That the association endorse the National Board of Medical Examiners, organized as outlined in the address of the president of the American Medical Association at its last meeting, and suggest the appointment by the president of the Mississippi Valley Medical Association of a committee of one from each State represented in the membership of the association to urge its adoption by the examining boards of their respective States, such committee to cooperate with any other committee working with a similar purpose."

Dr. John P. Compton of Branson, Mo., who is ninety years of age, claims to be the oldest practising physician in Missouri. He visits his patients daily and makes occasional trips into the country.

Surgeon George W. McCoy has been appointed director of the Hygiene Laboratory of the Public Health Service at Washington, D. C., succeeding Dr. John F. Anderson, who recently resigned to accept private employment. Dr. McCoy is at present in charge of the leprosy work in the hospital at Molokai, Hawaii, and is considered an authority on leprosy, bubonic plague and dengue.

Dr. George Chaffee of Bay Ridge, Brooklyn, the founder of the New York and New England Association of Railway Surgeons, was presented with a large silver loving cup at the twenty-fifth annual meeting of the organization, held recently in New York, at which over 200 members were present. Twenty-five years ago Dr. Chaffee called a meeting of railroad physicians and the society was organized with thirty-one charter members, of whom only ten are now alive.

Dr. John A. Pringle, assistant superintendent of the City Hospital, St. Louis, Mo., has been appointed temporarily to fill the post of superintendent left vacant by the resignation of the former incumbent.

Sir Charles Tupper, former Prime Minister of Canada, who died in England on October 30, at the age of 94 years, was a graduate in medicine from the University of Edinburgh, although he had long ago given up his profession for politics. He began life as a cobbler and, it is said, was as successful at making shoes as he was later as a physician and as a statesman.

Medical Society Elections.—The Mississippi Valley Medical Association, at its annual meeting held in Lexington, Ky., elected the following officers: *President*, William J. Stone, Toledo, Ohio; *First Vice-President*, Channing W. Barrett, Chicago, Ill.; *Second Vice-President*, Carl L. Wheeler, Lexington, Ky.; *Secretary*, Henry Enos Tuyle, Louisville, reelected; *Treasurer*, S. C. Stanton, Chicago, reelected. Indianapolis was chosen as the meeting place for next year.

Northern Berkshire Medical Association.—At the annual meeting held in North Adams, Mass., on October 19, officers were elected, as follows: *President*, Dr. Martin M. Brown; *Vice-President*, Dr. A. K. Boom of Adams; *Secretary*, Dr. R. D. Canedy; *Treasurer*, Dr. C. W. Wright; *Board of Censors*, Drs. F. H. Howard, G. H. Thompson, and J. H. Riley of this city, and Drs. Crowley and Pascoe of Adams; *Entertainment Committee*, Drs. O. J. Brown, G. H. Thompson, and M. M. Brown.

The Detroit Academy of Medicine, at the annual meeting held October 12, 1915, elected the following officers: *President*, Dr. Charles D. Aaron; *Vice-President*, Dr. Guy Connor; *Secretary and Treasurer*, Dr. Alpheus F. Jennings.

The Milwaukee Physicians' Association, at the annual meeting held October 14, 1915, elected the following officers: *President*, Dr. F. C. Malone; *Vice-President*, Dr. C. W. Graham; *Secretary*, Dr. S. M. Nullinger.

The Vermont State Medical Society, at its 102d annual meeting held at Burlington on October 14 and 15, 1915, elected the following officers: *President*, Dr. E. H. Ross, of St. Johnsbury; *Vice-President*, Dr. C. W. Bartlett, Bennington; *Secretary*, Dr. J. M. Hamilton, Rutland; *Treasurer*, Dr. C. F. Dalton, Burlington; *Auditor*, Dr. W. F. Hazelton, Bellows Falls; *Delegate to the American Medical Association*, Dr. Alan Davidson, St. Albans.

The South Texas District Medical Association, at its semi-annual meeting held at Nacogdoches on October 7 and 8, elected the following officers: *President*, Dr. E. A. Malsch of Victoria; *Vice-President*, Dr. C. C. Green of Houston; *Secretary and Treasurer*, Dr. M. F. Thomson of Beaumont.

The Minnesota State Medical Association, at its meeting in Rochester on September 30 and October 1, elected the following officers: *President*, Dr. J. Warren Little, Minneapolis; *Vice-Presidents*, Drs. J. J. Donovan, Litchfield, A. C. Rogers, Faribault, C. O. Wright, Luverne; *Secretary*, Dr. Thomas McDavitt, St. Paul; *Treasurer*, Dr. Earl Hare, Minneapolis; *Counsellors*, Fourth District, Dr. R. J. Hill, Minneapolis; Seventh District, Dr. F. A. Dodge, Le Sueur.

Obituary Notes.—Dr. Horace Greeley Norton of Trenton, N. J., secretary of the State Board of Medical Examiners of New Jersey, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1880, visiting physician to St. Francis' Hospital, Trenton, associate editor of *The Medicus*, and a member of the Medical Society of New Jersey, of which he was a former president, the Mercer County Medical Society, and the New Jersey Microscopical Society, died in St. Francis' Hospital on October 27, aged 57 years.

Dr. Joseph Jerome Noll of New York, a graduate of the College of Physicians and Surgeons, New York, in 1885, and a member of the New York State and County Medical Societies, died suddenly in his office, from heart disease, on October 17, aged 51 years.

Dr. Victor G. Becska of Passaic, N. J., a graduate of the Detroit College of Medicine, Detroit, Mich., in 1907, a member of the Medical Society of New Jersey, and the Passaic County Medical So-

ciety, and a former member of the Board of Health of Passaic, died at his home on October 25, aged 34 years.

Dr. AMZI JONES, formerly of New York, a graduate of Vanderbilt University, Medical Department, Nashville, Tenn., in 1900, and a member of the Society of the Alumni of Bellevue Hospital, and the Alumni Association of the Lying-In Hospital, died at Saranac Lake, N. Y., after a long illness, on October 23, aged 42 years.

Dr. TIMOTHY T. REGAN of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1884, died at his home on October 28, aged 54 years.

Dr. WILLIAM H. SCOTT of Brooklyn, N. Y., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1862, died at his home on October 27, aged 83 years.

Dr. PETER S. LEISENRING of San Diego, Cal., a graduate of the Pennsylvania Medical College, Gettysburg, in 1852, formerly of Omaha, Neb., and city physician, and a member of the Medical Society of the State of California, and the San Diego County Medical Society, died at his home on October 17, aged 86 years.

Dr. DAVID H. VAN NUYS of Anderson, Ind., a graduate of the Jefferson Medical College, Philadelphia, in 1864, died at his home just forty-eight hours after the death of his wife, on October 15, aged 79 years.

Dr. JOHN W. WILLIAMS of Clay City, Ky., a graduate of the University of Louisville, Medical Department, in 1887, and a member of the Kentucky State Medical Association and the Powell County Medical Society, died at his home, from cancer of the stomach, after a long illness, on October 13, aged 62 years.

Obituary.

JOHN HENRY HUDDLESTON, M.D.

NEW YORK.

Dr. JOHN HENRY HUDDLESTON, for many years secretary of the New York Academy of Medicine, died at his home, from pneumonia, after a short illness, on October 30, aged 51 years. Dr. Huddleston was born in Boston in 1864, and was educated at the Boston Latin School and at Harvard University, graduating from the Medical Department of the latter in 1891. He soon afterward came to this city, and shortly became prominent in civic affairs as well as medical. In 1903 he served as secretary to the American delegation to the fourteenth International Medical Congress at Madrid, and at about the same time was appointed a trustee of the State Hospital for the Treatment of Incipient Tuberculosis at Raybrook. He was also a director of the Metropolitan Life Insurance Company, and chairman of its welfare Committee. Dr. Huddleston was a visiting physician to the Gouverneur and Willard Parker Hospitals, and to the Riverside Sanatorium, consulting physician to the United Hospital, Port Chester, N. Y., and a member of the American Medical Association, the New York State and County Medical Societies, the American Public Health Association, the American Climatological Association, the National Association for the Study and Prevention of Tuberculosis, the Association of Military Surgeons of the United States, the Hospital Graduates' Club, the Society of Internal Medicine, the New York Pathological Society, and the Academy of Medicine. He was surgeon to the 7th Regiment, N. G. N. Y., from 1895 to 1907 and was retired with the rank of captain.

Dr. Huddleston was blessed with qualities which made him liked by all with whom he came in relation, and beloved by those admitted to his friendship. In medical practice he was the type of the perfect family physician. Of commanding physical presence, of firm will, but of most kindly and cheerful disposition, his mere entrance into the sick room inspired confidence and hope, and this went far to supplement his medical skill where cure was possible, and in bringing tranquility and comfort to those beyond human aid. In public life, both medical and civil, he was a model citizen, giving himself to every good cause without expectation of reward or thought of recognition. His scientific attainments were of a high order, though his many duties and extensive practice gave him little leisure for writing or public speaking. Dr. Huddleston's associates in every branch of his multifarious activities will feel an acute sense of personal loss in the untimely death of this unusual man.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL STAFFS AND THE WAR—RELATIONS OF TONSILS AND CERVICAL GLANDS—LORD MAYOR'S APPEAL FOR HOSPITAL FUNDS—STAR AND GARTER FOR RED CROSS—SWINE FEVER—OBITUARY.

LONDON, October 15, 1915.

THE war has taken so many surgeons from their usual work that a number of public institutions have been put to serious inconvenience. The residents at hospitals and infirmaries are specially qualified to meet the temporary demand and not a few have left those appointments for the army service. In one hospital a resident staff of twenty-nine was reduced to four. In another twenty-seven rapidly fell to eight. The hospitals with schools attached were in a better position as senior students could be employed rather more extensively than was customary before the pressure was felt. We have had an exhibition of apparatus for the treatment of fractures and other injuries. Officers of the R. A. M. C. who have served abroad have returned and demonstrated the uses of the many appliances and some interesting addresses have been given on the latest work as to wound infection and similar subjects.

The relation between the tonsils and the cervical glands is commonly looked upon as being too close to need remark, and indeed some seem to regard disease of the one as diagnostic of a corresponding condition in the other. Yet when a demand for direct evidence is made the response is not so ready as might have been expected and too often attention is directed only to hypertrophy when atrophy is of equal or even greater import. In 1909 Carmichael reported to the Royal Society of Medicine that out of 50 cases of chronic cervical adenitis the tubercle bacillus was present in the tonsils of 7. The atrophic sclerosed tonsils present wide open crypts for the entry of organisms. Mr. Gardiner, M.S., has been considering what evidence, if any, there is of the infectivity of the tonsils from the cervical glands where there is no obvious source of infection. In 30 cases organisms of some kind were found in 24; in the other 6 none, but it is possible

some were present in 4 of these as the guinea-pigs died too soon for the post mortem to have absolute negative value. The organisms were: *M. catarrhalis* in 7 cases, staphylococcus in 5, pneumococcus 7, streptococcus 7, *Bac. coli com.* 2, *B. tuberculi* 4, Friedländer's bacillus, 1. That in many cases glandular enlargement disappears after removal of tonsils is a familiar experience which seems to show their infectivity; but in some cases the enlargement remains after the operation. Partial removal is very unsatisfactory for the organisms almost always have penetrated to the deepest part of the gland, in fact the incomplete operation not seldom does harm. In 80 per cent. of Mr. Gardiner's cases without obvious source of infection the tonsils were involved, the small fibrotic variety being more dangerous than the larger. Tubercle bacilli are present in smaller proportion than commonly believed, but other organisms are often met with, suggesting that not a few cases passing as tuberculous are really septic.

The Lord Mayor issued his annual appeal for the Hospital Saturday Fund which has now been at work nearly half a century and has contributed £672,571 to the London medical charities. Last year it distributed 52,334 benefits: these include treatment at hospitals, at sanatoria and convalescent homes; provision of surgical appliances, first aid requisites and dental treatment. The total sum received in 1914 was £40,676. In all sections of its work the fund inculcates the principle of self-help. Its income so far this year is in excess of that for the same period in last year. If the fund has lost many supporters through the war, it has gained others at home who are engaged in munition and war work. The Hospital Saturday was October 9.

The Star and Garter Hotel is being converted into a permanent home for disabled and paralyzed soldiers and sailors, under the Red Cross Society. Rather, I should say, it is being rebuilt, as careful investigation indicated that a complete new building on the existing site would provide more beds at no greater cost per bed than the adaptation of the old premises. The Estate Agents' Institute is raising the necessary funds, holding sales in London and the Provinces of articles contributed for the purpose. The Queen has given an Indian silver casket for the first sale (November 10).

The investigations into the efficiency of serum injections in swine-fever which were being carried on before the outbreak of war have been continued. The results obtained corroborate those accumulated in other countries, seeming to show that with proper precautions immunity can be established by serum treatment. The Board of Agriculture therefore offer this treatment of pigs, free of cost, in the early stages of an outbreak. At the same time they impress on owners that to secure the best results from the treatment they should notify at the earliest date the existence, or even their suspicion of the existence, of swine-fever on their premises.

Captain A. E. Bullock, R.A.M.C., who was killed in action on the 27th ult., was one of the founders of St. Paul's School Mission and a distinguished sportsman as specially seen during his curriculum at St. Mary's Hospital. On the outbreak of war he received a commission and was appointed medical officer in the Middlesex (4th battalion) last year. He was mentioned in despatches in 1915, present at Round Hill 60, Ypres and Hooge. After a year's service he was promoted captain.

Progress of Medical Science.

The Boston Medical and Surgical Journal.

October 21, 1915.

1. Address. The Relation of the Medical Profession to Preventive Medicine. Haven Emerson.
2. The Syphilis We See but Do Not Recognize, and the Importance of Familiar Studies. Henry Farnum Stoll.
3. Some of the Anatomic-Pathologic Problems in Tuberculosis. Francis M. Pottenger.
4. Acute Otitis Media in Infancy and Early Childhood: Avoidable Mistakes in Diagnosis, Prevention, Treatment. William R. P. Emerson.
5. Can the Speech Present a Sign of Congenital Syphilis? First Note, Three Cases. Walter B. Swift.

2. The Syphilis We See but Do Not Recognize, and the Importance of Familiar Studies. — Henry Farnum Stoll gives the histories of thirteen cases that were not correctly diagnosed and concludes that the late symptoms of lues are often vague, but their indefiniteness should put us on our guard. "Chronic rheumatism" and "chronic headache" mean "chronic syphilis" in many cases. The physician who does not avail himself of all the newer tests before making these diagnoses assumes a grave responsibility. By carefully studying other members of the family some evidence of syphilis may be detected when nothing can be discovered in the patient himself. Of supreme importance is the realization that syphilis is a familial disease. It is a problem for the family doctor, not for the genitourinary specialist or the dermatologist. Finally we must not lose all sense of perspective and become blind worshippers at the shrine of Wassermann. Admitting that it is the most valuable laboratory test yet discovered, it is not infallible. Positive in nearly all early cases of syphilis it is often negative in the late cases, especially in adults with prenatal infection. Even when positive it does not prove absolutely that the lesion in question is due to syphilis. The Wassermann and luetin tests should supplement, not supplant, the complete history and careful examination.

3. Some of the Anatomic-Pathologic Problems in Tuberculosis.—Francis M. Pottenger read this paper before the American Climatological and Clinical Association. (See MEDICAL RECORD, October 2, page 588.)

4. Acute Otitis Media in Infancy and Early Childhood; Avoidable Mistakes in Diagnosis, Prevention, Treatment.—William R. P. Emerson believes that acute otitis media is the most frequently overlooked affection of infancy and childhood. It is not only not correctly diagnosed by the profession as a whole but it is also sometimes overlooked by the pediatrician, and in infancy its significance is often underrated by the aurist himself. Five cases were reported to illustrate the more common errors of diagnosis. In none of them was the symptom of earache present. In two the symptoms were all abdominal, in one meningeal, and in two general, associated with fever. In all of these cases the diagnosis was made by routine examination of the ear drums, not by localized pain or tenderness. Four of the five cases had a double otitis. Statistics given in 1912 by Dr. C. R. C. Borden, based upon a careful study of the clinical records of over 2,000 cases of scarlet fever, measles, and diphtheria at the Boston City Hospital and the pathological records of 252 autopsies performed by Drs. Councilman, Mallory, and Pearce, show that otitis media was clinically diagnosed in less than 15 per cent. of these cases, but in the 252 fatal cases otitis media was found present in 92 per cent. He concludes that in every case of contagious disease and every case of affection of the respiratory tract in children measures should be inaugurated at once to keep the nasopharynx clear and to maintain drainage through the Eustachian tube. In such cases the eardrum should be inspected at every visit of the physician to the patient. An electric ear instrument gives a clear picture of the drum with a

minimum disturbance of the child. In cases of otitis media when the symptoms and the local condition do not improve under treatment the drum should be incised by the aurist, if he is available; otherwise by the attending physician, without waiting for bulging or pus. Every child, after an attack of acute otitis media, should have his epipharynx examined and treated by a specialist trained to recognize the close relation of the nasopharynx to the ear.

5. Can the Speech Present a Sign of Congenital Syphilis? First Note; Three Cases.—Walter B. Swift reports these three cases for three reasons: First, he takes the clinical material in order that he may carry the investigation on to the final stages; secondly, because he wishes to inspire others to undertake the observations themselves; and, thirdly, that he may possibly be able by this form of presentation to divert a few cases to his own clinic for observation. From these three cases he concludes that there is a voice sign in congenital syphilis which manifests itself in a harsh, rasping, monotonous, low-pitched voice that is at most only slightly, and usually not at all, amenable to any sort of treatment. He believes that congenital syphilis can cause a faulty or incomplete development of vocal cords that results in vocal monotony and harshness in both conversation and weeping. As the term "spirochætosis" has been of late offered to cover all the lesions of syphilis he proposes as a name for this sign "scaphoid vocal cords and spirochætotic harshness."

1. Tuberculosis of the Patella.—Arthur J. Davidson says that on searching the literature on tuberculosis of the knee joint we are impressed by the comparatively small number of cases that are credited to primary disease of the patella and by the limited number of references to this specific subject. When we consider the frequency of primary tuberculosis of the various parts of the knee joint, it is surprising that the patella, in its close association with the knee joint, should be such an uncommon site for the primary tuberculous invasion. As a fitting conclusion to the presentation of this subject, the importance of early diagnosis in joint affections is emphasized and the prompt and efficient institution of remedial measures is urged. The opening of a knee joint is often regarded with fear and apprehension by surgeons who never hesitate to open the abdomen for similar purposes. There often seems to be a tendency to stand by and await developments when a joint is infected, thus allowing valuable time to elapse and the pathological process to advance. In many instances of infectious arthritis, the sooner the joint is opened and efficiently washed, the more favorable the prognosis. The earlier the treatment is instituted, the less likelihood is there to ankylosis. The diagnosis is often difficult, many times impossible. Under such conditions an exploratory arthrotomy is thoroughly justified. Great care and discernment are required in determining the advisability of recourse to operative procedure, for it must not be inferred that every patient with infection of a joint must necessarily be operated upon. The so-called expectant plan of procedure is essentially wrong and may be, generally, accepted as a confession of ignorance disastrous to the best interests of the patient.

3. Extragenital Chancres.—Henry Kennedy Gaskill says it is manifestly impossible to determine with any degree of accuracy the comparative frequency of extragenital chancres. The only place in which this could be approximately estimated would be in the army and navy; here careful statistics of all venereal diseases are made and the utmost care is taken to prevent their contraction. Unless there is a well-maintained correlation between the several departments that treat syphilis the value of statistics is entirely lost. As a rule in the histories of cases recorded as having been treated no reference is made to the situation of the chancres. The writer thinks we are prone to minimize the danger to which doctors and dentists are subjected, particularly the latter. With the modern ideas of antisepsis, the dentists of to-day are sterilizing each instrument after every patient, but this does not mitigate the risk of personal inoculation. For their own sakes, dentists should be trained to recognize the appearance of the mucous patch while in college. At present, to a very large extent, they obtain their information only from books, and colored plates, not from living patients.

7. The Phenoltetrachlorphthalein Test of Liver Function.—Max Kahn and James R. Johnston compare this test with certain other tests for the degree of functional activity of the liver. In one group of cases they performed the levulose test; in another the test for urobilinogen; and in a third group of cases they determined the urea, ammonia, and the aminonitrogen fractions of the urine. The determination of the nitrogen partition gave satisfactory results in several cases; *i.e.* in certain cases of known liver disease there was a decrease in the urea nitrogen and an increase in the ammonia nitrogen. The phenoltetrachlorphthalein test for liver functional activity is difficult of performance, and does not give any information that should be of clinical value.

8. Injuries to Bone at Tendon and Ligament Insertions without Local Tenderness.—A. H. P. Leuf considers this subject from a medicolegal standpoint and states that the important things to remember are, that no injury to ligament or tendon insertions to bone is too slight to receive serious consideration; that conditions fraught with the most distressing after effects may result from seemingly trifling injuries; that they may light up again and grow important after being seemingly well; that these exacerbations are largely due to the original strain or injury being much severer than is generally realized at the beginning; that augmentation of pathological conditions may be very slow because of negative circulation and low vitality of the parts, on which account they are also slow in getting well; that they are not affected by the usual medication if due to an injury; that the milder and chronic forms are not likely to evidence tenderness; that rest is the prime requisite in treatment during the acute stage; that electricity is the remedy par excellence after subsidence of the acute symptoms; that restoration of function must be preceded by easy stages of massage and light exercises very cautiously and judiciously practised; that relapses may readily occur; that congestion and inflammation may extend to adjacent parts, especially of the spinal nerves and cord when the spine is affected; that the simplest injuries may thus end in permanent invalidism; that it is never wise to assume complete recovery until it is proved by a clear demonstration of restoration of normal function, as shown by the resumption of full activity of the parts, and

its continuance for a number of weeks without noticeable bad effects.

10. Rectal and Anal Fistula.—Julius Frankel states that these lesions occur far more frequently than those of any other bowel disease, and that they are more frequent than all the diseases of all other abdominal organs combined. These fistulæ are most prevalent among the middle-aged and in individuals of robust type. They occur more frequently in men than in women, although dystocia is an additional factor in their etiology in women. One should never operate for a fistula when abscess is present, but incise the abscess and hint at a possible subsequent operation. At operation, locate the opening or openings and inject some coloring matter; then insert a grooved director and cut through all the overlying tissue, connect all tracts or branches with the main channel, never cut the sphincter in more than one place, dissect (but do not curette) all granulation and cicatrical tissue, and attend to the after-treatment of the patient yourself or appoint a good assistant. Never rely upon a nurse or orderly if you wish to avoid recurrence.

1. Antityphoid Vaccine.—Wilbur A. Sawyer presents the results of a study of antityphoid vaccination in civil life. He finds many statistics to prove the value of vaccination against typhoid fever in the army in this and other countries, but finds that it is meeting with a severe test among the civil population because the vaccine is most used where the exposure is greatest, and because only a small proportion of the people are vaccinated. Inquiry has shown that in California the true failures were 5,000 vaccinations reported, and the deaths from typhoid fever were 0.49 per thousand. The total number of vaccinations reported was 8,124. The percentage indicates a slight advantage for the Gay-Claypole sensitized vaccine over the unsensitized vaccines, but the superiority was not conclusively demonstrated as the different sets of statistics were not exactly comparable. There is little difference between the vaccines sensitized and unsensitized in common use in California with regard to the severity of reaction after inoculation. The extent of the exposure seems to be one of the most important of the factors which determine whether or not a vaccinated person will develop typhoid fever. If widespread and severe exposures are prevented by better supervision over public water, milk, and food supplies, vaccination can be depended on to greatly diminish the residual typhoid fever, especially if a large enough proportion of the people are vaccinated to reduce contact infection to a minimum.

2. Anesthesia. — Arthur Dean Bevan gives the results of an extensive study of the different methods of anesthesia based on observations in his own clinic, on pieces of laboratory work carried on by him and his assistants, on observations made in the clinics of others both in this country and abroad, and on a study of the literature. The final results of his analysis of the anesthetic problem are as follows: (1) Drop ether should be today chosen as the standard general anesthetic when a prolonged anesthesia is desired with relaxation and unconsciousness. (2) Intrapharyngeal ether should be chosen in mouth and jaw cases when it is desirable to remove the anesthetist and the anesthetic apparatus out of the operative field. (3) Gas should be chosen in short anesthesias in which unconsciousness is desired, and in special cases, such as kidney insufficiency. (4) Local infiltration anesthesia should be chosen when the surgeon has the full coopèration of the patient and when the field of operation can be completely infiltrated and anesthetized by a safe amount of novocaine and epinephrin. These four simple and safe methods can be made to cover all surgical cases and places anesthesia on a very simple unpretentious basis. Here as in most fields of surgery we learn that simplicity is near to truth.

3. Projectile Wounds of the Head. — Lloyd Mills states that he has drawn the material for this paper from the Vienna General Hospital where he had charge of two wards devoted to the care of the wounded and especially of eye and head injuries. He also states that he has gained much interesting matter from the army surgeons relative to the rapidly fatal wounds seen on the firing line. Because of the position of the men in the trenches wounds of the head are probably the most frequent of all injuries, their frequency being masked in the hospital lists of wounded by the fact that fully 95 per cent. of all short-range wounds of the head are immediately fatal because of the literal ruin which the modern sharp nosed bullet makes of the cranium and its contents. Facial wounds of every description are very common and may be serious if the eyes are involved or mastication is impaired. Reconstruction of skulls shattered by the modern pointed bullet shows that the undeformed bullet passes completely through the skull and emerges before the collapse of the cranium occurs. When the missle is deformed the effect on the head is the same as on the rest of the body, tremendous laceration and loss of tissue. The most frequent type of bullet wound as well as the most disfiguring wound of the orbital region was that in which the antero-external wall of the orbit was cleanly shot away, the bulb always being ruptured. In many cases in which bullets struck or perforated the orbital cone, without touching the globe, the globe was shattered by indirect violence. One of the most interesting and important facts in connection with the mechanism of the production of the bullet wounds is that the injury to the bulb is seldom, if ever, in a direct line with the line of incidence of the blow, but is usually nearby at right angles to this line. Probably scrapnel and other shell explosions are the most frequent cause of unilateral blindness and lead most frequently to enucleation. The common rule in cases of perforating wounds produced by shell fragments is prompt enucleation where there has been material damage and when fragments of any size are lodged in the globe and are not easily accessible. About one-sixth of their eye cases were those in which the strain of hard campaigning on insufficient food and exposure to weather and filth conditions had produced the same ocular diseases which might be expected under similar strain or exposure in civil life. The author feels confident that one sequel of the war will be the extension of trachoma. A very prominent group of cases are those of bilateral blindness. Every clinic is

furnishing its quota of these pitiful cases, nearly all young, strong men, so overwhelmed by their misfortune that they often accept any means of suicide as an escape. The frequency of this terrible injury should, alone, lead to the abandonment of the spitzer bullet, or to its modification.

4. **Gall-Bladder Infections.**—W. Wayne Babcock divides gall-bladder infections into four types, according to the mode of invasion, and states that the diagnosis of cholecystitis, even after opening the abdomen, is not always easy. In making the diagnosis he depends on signs of alteration in the color, size, or consistence of the walls of the bladder; adhesions or other evidence of pericholecystitis; enlargement of the tributary lymph-nodes, though these may also occur from pancreatic or duodenal disease; alterations in the bile contained within the gall bladder, and alterations in the mucosa. Inflammations of the gall bladder are, in the opinion of the author, bacterial infections of childhood or early adult life, progressing for years, during which time secondary metastatic, toxic, or reflex symptoms only are observed; later they have a second stage in which there are attacks of colic due as a rule to the presence of gallstone, and usually a third stage, generally after twenty or thirty years, of serious complications, such as obstruction, pancreatitis, perforation, abscess, or gangrene. Surgery works for the most part far behind the pathology of the disease and there is wide need for earlier intervention so that the patient who starts at the age of twelve or fifteen years with cholecystitis and dyspepsia may not at thirty-five have gallstone colic and at sixty-five succumb to cholecystitic gangrene or pancreatitis. External biliary drainage is as a rule undesirable, except in late or complicated cases. Early cholecystectomy is the operation of choice. Technical dangers make uniform success after cholecystectomy uncertain in the hands of the average surgeon. Notwithstanding this, the mortality of cholecystectomy in the first stages of cholecystitis is much less than cholecystotomy in the last stages of the disease.

5. **Blood Serum.**—Charles L. Tranter and Albert H. Rowe describe their work in the refractometric determination of albumin, globulin, and non-protein in normal human blood serum. The Robertson method has advantages over that of Emil Reiss. In normal individuals the authors find that: 1. The total proteins range between 6.7 and 8.7 per cent., which corresponds to the figures of Reiss. 2. The total albumins lie between 4.95 and 7.7 per cent., with an average value of 6.20 per cent., or between 67 and 89 per cent. of the total proteins, with an average value of 78 per cent. 3. The globulins lie between 1 and 2.54 per cent., with an average value of 1.74 per cent., or between 11 and 33 per cent. of the total proteins, with an average value of 22 per cent. 4. The non-proteins lie between 0.98 and 1.19 per cent., with an average of 1.09 per cent., and have a refractivity varying from 0.00158 and 0.00190, with an average of 0.00175. No definite differences can be noticed in the results due to the age of the subjects. The percentage of globulin was consistently higher in the women examined than in the men.

10. **Hemorrhagic Myelitis.**—Benjamin T. Burley reports a case of acute ascending hemorrhagic myelitis, which seems to occupy a unique place allied to, but not identical with, either myelitis or hemtomyelia. The author reports two other cases which show the clinical resemblance of hemorrhagic myelitis to acute ascending paralysis, either of the poliomyelitic or Landry's type. Though this resemblance is striking, a closer analysis of symptoms and pathological findings points to the existence of three distinct types of acute ascending paralysis. The further confirmation of these types await laboratory differentiation which seems near completion.

1. **Science and War.**—Sir William Osler, in an address delivered at the University of Leeds on October 1, 1915, declares that the race is in one of its periodic attacks of acute mania. So respectable and self-respecting had we become that the bout is a great shock, but the lust of war is still in our veins and we cannot help it. The explanation of this distressing fact is that we are still in the childhood of civilization. In time our civilization is but a thin fringe, like the layer of living polyps on the coral reef, capping the dead generations on which it rests. We must get the race in its true perspective in which a thousand years are but as yesterday, and in which we are contemporaries of the Babylonians and Egyptians, and altogether within Plato's year. Dr. Osler reviews the events of the past century which fostered the hope that humanity had lifted itself to a level on which might be realized the brotherhood of man, outlines the results of scientific progress, and shows more particularly how scientific methods have been utilized by man for the destruction of his kind, and how, on the other hand, science has been employed as a beneficent force in the care of the wounded. He then asks the question "Is science for or against humanity?" and answers as follows: "War is more terrible, more devastating, more brutal butchery, and the organization of the forces of nature has enabled man to wage it on a titanic scale. More men will be engaged and more men will be killed and wounded in a couple of years than in the wars of the previous century. To humanity in the gross she seems a monster, but on the other side is a great credit balance—the enormous number spared the misery of sickness, the unspeakable tortures saved by anesthesia, the more prompt care of the wounded, the better surgical technique, the lessened time in convalescence, the whole organization of nursing; the wounded soldier would throw his sword in the scale for science—and he is right." Dr. Osler believes that one of the sequels of the war will be, for this generation at least, the death of international science, and that the final deliverance from strife will not be in our day, but holds out the hope that, as the history of our ancestors in all times and countries has been one of incessant and successful adjustments, one may take a "Pisgah-sight" of a day when "nation shall not lift up a sword against nation, neither shall they learn war any more."

2. **War and the Medical Education of Women.**—Florence E. Wiley, in an address delivered at the opening of the London Royal Free Hospital School for Women on October 1, 1915, says that it is becoming obvious to everyone that there is a very vital connection between the war and women's work. The summons to women to fill up the ranks has come to all kinds of professions and trades, but in none is the demand more urgent than in the medical profession. War has taxed the resources of the profession to the utmost by directly absorbing the services of many thousands of doctors,

but in more indirect ways the war is creating a future need which threatens to be very serious indeed. It means for years to come a decreasing number of men in the medical profession. Some are fearing that the calling of women to new pursuits involving physical and intellectual powers to an extent unknown before may not be compatible with the fulfilling of the country's great need of a sane and stalwart race. This fear is groundless; the new order of things will be a help and not a hindrance to race development. As to medical work after the war, there will be need for more medical people in the public services if a thorough system of preventive medicine is to come into being. There will be a wide field in the study and care of pregnancy, the art of obstetrics, the preservation of child life, and the prevention of such diseases as hinder conception, kill the unborn, maim childhood, and produce chronic invalidism in women. If such work had been successfully prosecuted forty or fifty years ago it would have given England today more than a million of men of military age and an equal number of young women to spend their strength in the service of their country; these have perished, for every year at least 100,000 infants are lost during the first year of life and 150,000 more perish from ante-natal causes. These subjects involve a type of research which has been comparatively little recognized in medical circles but which is every day becoming more essential to the success of preventive medicine.

4. **Amputation by Plane Circular Section.** — G. A. Wright is of the opinion that this method of removing a limb is being employed more frequently than is sanctioned by authority. The state of the stumps in the cases admitted to the hospital since May, 1915, has driven them to consider whether it is desirable that this procedure should be continued. The stumps show a large area, sometimes several square inches of granulating surface with bone exposed and protruding more or less beyond the level of the soft parts. There is great delay in healing, and the process is either incomplete or, at best, a large thin cicatrix results. In considering these cases it has been found that the practice has not been limited to cases of gas gangrene, but has been employed in cases of secondary hemorrhage, in septic arthritis, in patients whose limbs have been shattered, and in gangrene of the ordinary type following ligature of a main artery. Either a flap operation or an oblique section provides quite as free drainage as does a plane circular section, or the flaps may be fixed open for a time and brought together when it is safe to do so.

5. **Septic Compound Fractures.** — Vernon Pennell states that the unsatisfactory condition of so many old compound fractures that have come under his observation since the commencement of the war have encouraged him to embark on a rather more radical treatment of these cases. He is now strongly of the opinion that some means of internal splinting should be carried out in all compound fractures where (a) an incision is needed for ample drainage and efficient cleansing and (b) where the skiagraph shows malposition with conservative treatment. The method he adopts is to make a large incision over the site of the fracture; define the ends of the bone; remove any small detached portions of bone and shrapnel; and, after placing the two or more main fragments in position, either fix them with a Lane's plate and suture them with silk worm gut; or, where there is much loss of bone, transpose a graft from the tibia or fibula. If the wound is septic no attempt is made to bury the plate or fixing apparatus. So far results have been most gratifying. There has been a saving of time, almost complete absence of pain, and rapid formation of callus, even in spite of suppuration. The writer finds that: 1. Foreign bodies, even when septic, can be rendered sterile and are tolerated by the tissues. 2. Position is almost as good as that of a simple fracture treated by plating. 3. Dressing is facilitated by a "fixed" fracture even though the fixation be but partial. 4. Function is better than by other methods.

6. **Intestinal Drainage in Septic Peritonitis.**—Arthur J. Nyulasy believes that in septic peritonits the deterioration and death of the patient is unquestionably due—in many cases largely and in others almost entirely—to intestinal toxemia resulting from the acute stasis. The rational treatment of this toxemia is the removal of unabsorbed intestinal toxin and the prevention of its further production. Both of these ends may be secured by intestinal drainage, provided that the peritoneal cavity is not charged with excessive poison and that the focal factor is eliminated. He reports six cases of post-operative septic peritonitis treated in this way, all of which recovered. He is convinced that these results could not have been achieved by any other known method.

6. **Complete Branchial Fistula in an Adult.**—C. Hamilton Whiteford reports this case which occurred in a sergeant, 32 years of age, who was admitted to the hospital three and one-half months after having sustained a compound fracture of the inner end of the right clavicle. At about an inch above the right sterno-clavicular joint, at the inner edge of the sterno-mastoid, was a minute opening in the skin, from which exuded a clear glairy fluid. A fine lead probe passed into the sinus could be inserted upwards and backwards for five inches, and its end could be felt behind the tonsil. Methylene blue solution injected into the sinus caused immediate blue coloration of the saliva. Through a skin incision 4½ inches in length the tube was dissected intact up to its pharyngeal attachment. The removed tube was lined by mucosa and when lying flat measured one-half an inch in width. Microscopic section showed a thick outer layer of longitudinal muscle fibers, a thin middle coat of connective tissue, and a lining of mucosa. The patient made an uneventful recovery.

6. Acute Actinomycosis of the Parotid Gland. E. D. Telford.

1. **The Value of Hypochlorous Acid in the Treatment of Cases of Gas Gangrene.**—John Fraser states that he has never seen a gas infection follow a wound of the scalp or face, and on only one occasion has he seen it follow a wound of the trunk. It is seen more frequently in the lower extremity than in the upper, and in the lower limb the seat of election of the infection is certainly below the knee. The infection occurs most frequently in a punctured wound, and more especially in a wound which has been associated with extensive extravasation of blood into the tissues. In the treatment of these cases the writer has been making an application of 0.5 per cent. solution of hypochlorous acid, known as eusol, occasionally intermitted by the application of a powder known as eupad (bleaching powder and boric acid), and the use of baths of hypertonic salt solution. The eusol treatment was begun immediately upon the recognition of the condition. The local wound was opened up freely, all free blood clot removed, and wound thoroughly irrigated with eusol. Grossly in-

fected muscle or skin was cut away. Gauze soaked in eusol was packed lightly as far into the wound as possibly. If the wound was of considerable depth, a medium-sized drainage tube with large lateral openings was inserted, and around the tube gauze wrung out of eusol was packed. Eusol dressings were applied over the wound and over a large area of the surrounding skin. In two cases in which a slight irritation appeared around the edge of the dressing, it was speedily alleviated by the application of a thick layer of zinc ointment. Dressings were changed at first every four hours and later every eight hours. The writer's experience shows that granulation tissue is improved and the separation of the slough stimulatd by the application of eupad to the wound on the fourth day and continued through the fourth, fifth, and sixth days. On the seventh and subsequent days, until granulation is complete, the part was immersed for four hours each day in hypertonic salt solution. The eusol at no time produced pain or irritation; the same could not be said of the eupad. The general condition of the patients improved synchronously with the improvement in the local condition. The author reports nine cases of intense severity treated successfully in this way.

3. **Acute Renal Disease among the Troops in France.**—R. G. Abercrombie gives an account of 95 cases of renal disease that have come under his personal care among British troops serving in France. The disease exhibits the features of an acute nephritis. The majority of the cases occurred in previously healthy young or middle-aged men, in whom no evidence of pre-existing renal disease could be found. In a small minority of cases the previous history or the presence of cardiovascular changes led one to suppose that the condition was superimposed upon previously damaged kidneys. The onset of the disease was sudden. The symptoms presented were edema, albuminous urine containing granular casts, febrile reaction, and uremic symptoms. The blood pressure was usually high. None of the patients died. After a stay in the hospital of from one to three weeks, 92 of the patients were transferred to England free from edema; in a few the albumin had disappeared, in others it was reduced to a trace, but the majority were still passing a fair amount. Three cases assumed a chronic aspect. The treatment was similar to that usually given in acute nephritis. After reviewing all possible circumstances with reference to the causation of the condition, the writer is inclined to the belief that the disease is an infection by a definite organism, the nature of which is at present undiscovered.

4. **The Importation of Bacillary Dysentery.**—A. E. Carver expresses the belief that as cases of dysentery are being sent from the front these are likely to be followed by similar epidemics among the civil population. He recalls that such a sequence occurred in North London in 1902 and that Dr. Cautley has described an outbreak among women and children which occurred at a London barracks in June, 1900. Previous experiences should make clear the necessity for the adoption of stringent methods of precaution and prevention, because when the disease once gains a foothold it proves to be of a virulent type, the rate of fatality, among children especially, being extremely high.

6. **Acute Actinomycosis of the Parotid Gland.**—E. D. Telford reports two cases of infection by the ray fungus in which the swelling and induration, which is usually of gradual development without acute local or general reaction, assumed a much more acute form than is ordinarily the case. The features of this acute form of actinomycosis appear to be that the infection enters by the parotid duct, and within a few days gives rise to an acute parotitis. The disease then bursts through the limits of the gland, whereupon a very acute cellulitis develops which may extend far over the scalp and well down the neck, and which is accompanied by great constitutional disturbance and marked evidence of septic absorption. Any acute cellulitis of the face of obscure origin should excite suspicion of actinomycotic infection. The discharge from such lesions, or, better, a small piece of tissue, should be examined, and a single negative result should by no means be accepted as final. Early and energetic treatment is imperative if the patient is to be prevented from drifting into the ordinary chronic form of the disease.

Berliner klinische Wochenschrift.

September 13, 1915.

Brain Lipoid as a Hemostatic.—Hirschfelder of Minneapolis contributes this article. He refers to the discovery of Howell that the so-called fibrin ferment is not really an enzyme, but a lipoid, which is probably none other than the "kephalin" described many years ago by Thudichum. As is well known, the fibrin ferment prepared from blood platelets has hemostatic properties and is at present extensively employed for this purpose. Hess has used extracts of brain as styptics. It should be possible to prepare hemostatics from brain substance on a large scale for use in the present war. The author has made lipoid extracts by placing the brains of one or two oxen in threefold the amount of alcohol, shaking and decanting. The residue is now gently strained through muslin and treated with threefold the amount of ether, shaken violently and filtered through cotton and paper. The dried filtrate is yellow, consists of Thudichum's kephalines and possesses strong hemostatic properties, through its power of accelerating coagulation. Even traces of lipoid show this power *in vitro*. So marked is this property that the author attempted to control parenchymatous hemorrhage without the ligation of vessels. A drawback was soon apparent in the sudden formation of large clots, and despite the power of the lipoid it was found that all arterial trunks should be ligated, one by one. To prevent the sudden and voluminous clotting, the lipoid should be spread on gauze. The author announces in closing that Horwitz of San Francisco has independently reached the same results with pure kephalin.

Aleukia Hemorrhagica.—Frank writes at length on this subject, in association with aplastic anemia and thrombopenia. Aplastic anemia again is associated with a general wasting of bone-marrow (panmyelophthisis). Clinically these pathological states are expressed as a chronic idiopathic Werlhoff's disease, which may be comprehended as running four different courses. The first is intermittent thrombopenia with normal blood count in the intervals. During the crisis the blood plates are diminished. The author has seen two cases of this type. The second course pursued is that of continuous thrombopenia. The bloodplates are very sparingly present. The tendency to hemorrhages is constant. In general the blood picture is that of chloranemia. In the third type continuous thrombopenia is associated with aplastic anemia, and in the fourth and last type the condition is aplastic anemia from the outset. The author would substitute the term aleukia hemorrhagica for aplastic anemia, because the latter is not a primary condition due to hemolytic toxins derived from the red cells. The anemia is largely post-hemorrhagic and the toxicosis does not attack the red cells but the leucocytes and marrow. The condition has no connection with ordinary secondary

anemias nor with the Biermer type. Aleukia means really an absence, complete or nearly so, of the blood platelets. That a toxicosis is at fault is clear from the fact that aleukia hemorrhagica is seen as a result of arsenic poisoning, typhoid fever, benzol poisoning, Roentgen rays, and thorium X.

September 14, 1915.

Therapeutic Use of Colloidal Silver.—Voigt seeks to find a criterion which will remove this substance from the "post hoc" class, for in practice thus far it has been impossible to state whether or not it really cures septic conditions. It cannot long remain in the circulating blood and is deposited in the liver, spleen, and bone marrow in which it maintains a certain relationship to the blood as it passes through them. For a considerable interval, however, it persists in the blood in a very low but apparently constant concentration, and may be able to exact an ionic or catalytic action. It is evident that little, if anything, is to be gained by injecting it in high concentrations. A ½ per cent solution should suffice, with total disregard of isotonicity. If the particles are of a sufficient size capillary embolism can result. There is no doubt that at times it acts brilliantly in septic and pyemic conditions. It is essential that it be given early, although the author saw one remarkable cure of pyemia when the drug was given as a last resort. There is no doubt of its value in the selected case although the author does not lay down any postulates for selection. The ointment has a field in local infections.

Arsenical Keratosis Following Salvarsan Injections.—Philip calls attention to the fact that but few cases of salvarsan by- or after-effects are to be attributed to the arsenical component of the latter, and in such cases there is a "relative overdose" of arsenic or an arsenic idiosyncrasy. A not uncommon result of ordinary arsenical medication is a tylosis of the palms and soles, usually consequent upon long-continued exhibition of the drug, but perhaps exceptionally conditioned by imperfect elimination. The author's patient was a small, delicate woman, recently confined who had received too large doses of salvarsan for her weight, and was moreover a victim of latent tuberculosis. The scanty urine of the patient also pointed to a defect of elimination. She had received two doses of neosalvarsan, which aggregated nearly one gram.

Detonation Labyrinthoses.—Hoffmann is in charge of an ear station at Lille and has had opportunity for the study of 50 cases of detonation injuries of the ear. In all instances of labyrinth disease there was demonstrable some disturbance of sensibility in the external ear, which should have been absent in disturbances of conduction in otherwise normal patients. These censory derangements were certainly not of hysterical origin, nor do they come under the head of traumatic psychoneurosis, for the patient's frame of mind was cheerful at the moment of injury. The cochlear nerve was doubtless the seat of the traumatism, especially as the vestibular nerve showed few signs of involvement. The victims were at once put to bed and given 25 drops of tincture of valerian three times daily. Bromides would have been unnecessarily strong for such cases. These patients should practice lip reading, and should also read much. The attendants should speak in low tones. If there has been rupture and infection of the middle ear—and in these cases this affection usually pursues a severe course—there should be no meddlesome intervention. Only a sterile pledget of cotton should be placed in the external ear.

Deutsche medizinische Wochenschrift.

September 16, 1915.

Hodgkin's Disease with Pemphigus and Granulomatous Nodules in the Skin.—Hoffmann relates a case of typical Hodgkin's disease to which were superadded pemphigus and a granulomatous infiltration of the skin. The enlarged lymph nodes of the disease proper and the skin tumors responded promptly to the *x*-ray, but the pemphigus continued to progress during this period and was pronounced to be of separate origin. After a month of latency an exacerbation of the glandular tumors followed, but was not pronounced. Tuberculosis was thoroughly excluded. The skin tumors were recognized as an essential part of the disease while the pemphigus was deemed to be of mechanical origin, aggravated by the rays.

Therapeutic Typhoid Vaccination.—Reiter sums up his experience as follows: In carefully and individually regulated doses typhoid vaccine injected repeatedly does not aggravate the disease picture, and in the majority of cases exerts a favorable influence on the course of the disease, which it abbreviates, with reduction of mortality. There is usually a reduction of temperature in the cases which show improvement. If the temperature is not brought down by the treatment the prognosis is unfavorable. The action of the vaccine on the disease cannot be termed decisive, and moreover no influence whatever is exerted on complications—they are neither prevented nor benefited to any marked degree. The results in the main are sufficiently good to add the vaccine treatment to the other dependable measures hitherto in vogue. Complications form no contraindication. Repeated small injections are to be preferred to a single one of large dose. There is no corresponding advantage in giving large quantities.

Uremia.—Machwitz and Rosenberg reach conclusions which agree closely with those of other recent writers. We see the essential form, the azotemia in the acute glomerulonephritides, and in both secondary and idiopathic contracting kidneys. The diagnosis is best made by direct blood tests for indican and retained nitrogen. The principal feature in treatment is a low protein diet. So-called eclamptic uremia, characterized chiefly by the preponderance of uremic convulsions is seen most commonly in the nephritides of the young. The prognosis is in general good and the chief therapeutic resource is lumbal puncture. The third form is the pseudouremia of atherosclerosis affecting the vessels of the kidneys, and is not a true uremia because due to cerebral atherosclerosis. There is no retention of nitrogen in the blood and no indicanemia. The therapy must be that of arteriosclerosis, such as dietetic restriction of fluids.

Functions of the Spleen.—Hirschfeld sums these up as follows: In man the organ makes blood elements—lymphocytes and large mononuclears. The entrance of these into the circulation has not yet been observed. In anemias, leukemias, and infectious diseases, the spleen can form erythrocytes and granulocytes. The organ under normal conditions destroys erythrocytes and the hemoglobin becomes the bilirubin of the liver. The spleen regulates iron metabolism as well as hemoglobin metabolism. It is the "regional lymph node" of the blood, and generally speaking destroys all particulate bodies which have fulfilled their uses as well as foreign particles which have reached the blood, including bacteria. It also is the source of bacteriolysins, etc. For these reasons it always enlarges during infections. The spleen also exerts a regulating action on the formation of erythrocytes on the bone marrow. It has certain relations to digestion not yet understood.

Insurance Medicine.

Periodical Examinations of Apparently Healthy Subjects.—Florschütz gives a concise account of the activities of the Life Extension Institute of New York. This movement has been practically ignored in the German special periodicals, despite its manifold interest for physicians, racial hygienists, socialists, etc. The author bases his digest, at least in part, on an address delivered by Dr. Fisk of the Institute before the Kentucky State Medical Society in September, 1914. The citations close with the table of morbidity compiled from results of first examinations of numerous insurance risks and employees of banks and corporate bodies. Florschütz now states that the various percentages for diseases and defects do not necessarily hold good for greater material. For example one would not expect to find a high percentage of tuberculosis in such selected material. On the other hand the figures on high blood pressure and traces of albumin in the urine cannot be straightway regarded as unfavorable prognostics. But the proportion of actual arteriosclerosis in relatively young subjects (over 13 per cent. in clerks) is most serious, and if nothing else had been disclosed by the work of the Institute this discovery alone would have justified the effort. This pathological state does not in any way differ from arteriosclerosis after 50, and by terming the latter partly physiological great harm results, expressed in a heavy toll of deaths from cardiovascular disease in those still middle aged. Florschütz appears just a little suspicious of these figures; at least he would not pronounce a youngish man an arteriosclerotic until he had been repeatedly examined and by more than one examiner.

The campaign against tuberculosis has been an aid to this life extension movement, in that it has helped to popularize such methods; but bad as tuberculosis is, arteriosclerosis is worse; for as we know nothing of its actual causes we are thus far powerless to prevent it. The work of the Institute may throw light on it and the numerous affections associated with it.

Physicians in general, who will be called in to treat these ailments, must educate themselves to the new point of view of prophylaxis or at least change their old point of view in these matters which has been one of *laisser aller*. If the general practitioner does not take his responsibility seriously, the movement would not repay the output of time, pains, and money. When the family physician of a man pronounced by the Institute to be ailing in some respects, is made aware of the fact his natural inclination might be to belittle the find. He would do better, however, to go over the ground himself. The condition discovered may be transitory or so slight as to yield promptly to treatment. It would be going much too far to see in this almost universal morbidity of selected men evidence of physical decay. The physician must always be an optimist. Man as a whole is not spoiled and the efforts of the Institute should tend to give him a higher physical and moral status and work hand in hand with eugenistic movements.

In its essence the Life Extension movement is not new. Life Insurance companies have off and on made provisions to treat their insured, as well as instruct their risks in hygiene, especially in connection with tuberculosis. Any examination of an applicant by the Medical Board of an Insurance Company is an examination of an apparently healthy subject, and when he has been postponed and treated for an ailment he can be reexamined. Life insurance, of course, is not interested in racial biology, nor in breeding supermen, but its selfish interests militate against the common accusation that efforts to conserve the race save the weaklings. She is not looking for a gift from the Danae. —*Blätter für Vertrauensärzte der Lebensversicherung*, May-August, 1915.

Traumatic Neuroses Calling for Compensation.—These conditions form a group of disorders which are a frequent source of litigation with reference to compensation. Sir Thomas Oliver brings out this point in a paper on the "Rôle of Traumatism in Disease Calling for Compensation," read before the Assurance Medical Society of London, May 5, 1915. A patient has been in a railway accident or a motor-car collision and his nerves have been shaken up and perhaps he has been rendered unconscious. His nervous symptoms resemble those which used to be described under the term of "railway spine," a condition for which, apparently there exists no anatomical foundation. The patient is in a state of broken-down health, unfitted for work, complains of ill-defined pains and loss of power in the limbs. He seeks for monetary redress from those whom he regards as culpable. One of the most rapid cures for the ill-health which has followed a railway injury is settlement of the claim. Non-payment keeps the victim in a state of uncertainty and worry caused by repeated medical examinations and the malady does not improve, but drags on, the individual becoming less and less inclined to undertake work.

Shock to the nervous system produces disordered sensation which is the outcome of either altered function or of changed structure. Is disease the expression only of altered structure or is it not rather that structural changes are the consequence of aberrant function? Death frequently occurs without any structural change being found at autopsy to explain it, as in cases of lead poisoning where the patient dies before time has been given for structural changes to have taken place.

This also brings up the question of compensation where illness and incapacity to work are caused by the association of gout and plumbism. Plumbism is a scheduled disease, and if it has caused gout why should the patient with gout due to lead not be compensated? Here heredity and mode of living have to be taken into account as such conditions influence the production of gout. On the other hand if a patient is to be compensated for loss of work caused by lead colic, a condition usually of short duration, why should not the man who is suffering from gout consequent upon lead poisoning, a more enduring illness than lead colic, receive some monetary consideration? Gout as a sign of plumbism is not on the same level as "wristdrop."

Since the Workingmen's Compensation Act came into operation the length of time required for the healing of a fractured limb is much greater than it was twenty-five years ago, showing the unwillingness on the part of the injured to return early to work. Insurance companies occasionally do harm by not paying injured men promptly and by not paying a lump sum down. This is a financial question which must be settled by experience. The rate at which traumatic neuroses are increasing among female workers in all trades is a noticeable feature of modern industrial life, and for this the Workmen's Compensation Act is partly responsible.

Book Reviews.

Outlines of Internal Medicine for the Use of Nurses. By Clifford Bailey Farr, A.M., M.D., Instructor in Medicine, University of Pennsylvania; Assistant Visiting Physician, Philadelphia General Hospital; Pathologist to the Presbyterian Hospital, etc. Illustrated with 71 engravings and 5 plates. Price, $2.00. Philadelphia and New York: Lea and Febiger, 1915.

It is now recognized by the medical profession that a competent nurse requires to be trained in a systematic manner in medicine. That is to say it is necessary, for the proper carrying out of her duties, that her knowledge of medicine so far as it goes, should be thorough. The work by Dr. Farr presents the outlines of internal medicine in detail. He has confined his consideration to essential points and has dwelt upon and made clear such facts as will be most useful to his readers. While the book takes a comprehensive grasp of the entire subject the most important features as far as the nurses' standpoint is concerned are duly emphasized and the result is that he has been successful in compiling a valuable text. The work is well illustrated.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By Oliver S. Ormsby, M.D.; Professor and Head of the Department of Skin and Venereal Diseases, Rush Medical College (in Affiliation With the University of Chicago); Dermatologist to the Presbyterian, Children's Memorial, Saint Anthony's and West Suburban Hospitals, the Home for Destitute Crippled Children, and the Orphan Asylum of the City of Chicago; Member of the American Dermatological Association and of the Congress of American Physicians and Surgeons. Illustrated with 303 Engravings and 39 Plates in Colors and Monochrome. Price, $6.00. Philadelphia and New York: Lea & Febiger, 1915.

This is a comprehensive treatise on a subject which has undergone considerable development within recent years, particularly in the differentiation of new types of cutaneous disease and the more accurate delineation of the older types. The work is an eminently practical exposition of the common as well as of the rare forms of skin disease; the etiology, pathology, and diagnosis are fully discussed; and the treatment is presented in sufficient detail to satisfy the needs of the general practitioner and of the specialist. The literature is freely drawn upon and this together with the author's own extensive clinical experience makes the volume one of unusual completeness and accuracy. The illustrations are numerous and of a high order of artistic merit. The thirty-nine full page plates comprise in themselves a small atlas of skin diseases.

The Clinics of John B. Murphy, M.D. Volume IV, Number II (April, 1915). With 47 illustrations. Published bi-monthly. Price per year: paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1915.

The initial chapter of this number on surgical diagnosis is concerned with acute osteomyelitis. The points in diagnosis and the necessity for prompt and adequate treatment, as well as the proper method of handling these cases when seen at a later stage, are brought out in clear-cut fashion. A valuable chapter is contributed by Dr. William L. Rodman, of Philadelphia, and deals with carcinoma of the breast. The first part of the talk is taken up with a consideration of precancerous conditions in the breast, particularly chronic cystic mastitis, or, as he prefers to call it, abnormal involution, as suggested by Warren, of Boston. An analysis of 200 cases of breast operations in his private practice is then given, followed by a description of his operative technique, with illustrations, and a short statement, with analytical table, of ultimate results.

Student's Textbook of Hygiene. By W. James Wilson, M.M., D.Cs., D.P.H. Bacteriologist to the Counties of Down and Antrim; Lecturer on Hygiene and Public Health, Queen's University, Belfast. Price, $2.50. New York: Rebman Company, 1915.

This textbook deals only with the fundamental principles of the science of hygiene. The subject matter is presented in a very clear and interesting manner and should prove of great value to students, teachers, sanitary inspectors, health visitors and all interested in public health work. The author is especially to be congratulated on the clear and lucid way in which he has presented the subject of "Infection and Immunity." Other chapters deal with animal parasites, heredity and eugenics, air, soil, water, food, buildings, heating, lighting, ventilation, disposal of excrementitious material, personal hygiene, school hygiene, communicable diseases, tropical diseases, sanitary law, disinfection, the prevention of infectious diseases, and vital statistics. The details of analysis of foods, water, air, etc., are omitted since these can be properly learned only in a laboratory. Twenty-six figures help to elucidate the text. For one wishing a summary of the subjects treated drawn from reliable sources this book will prove very valuable.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger, June, 1915.

This number of "Progressive Medicine" contains articles on Hernia, by W. B. Coley; Surgery of the Abdomen, exclusive of Hernia, by J. G. A. Gerster; Gynecology, by J. G. Clark; Diseases of the Blood, Diathetic and Metabolic Diseases; Diseases of the Thyroid Gland, Spleen, Nutrition, and the Lymphatic System, by A. Stengel; and Ophthalmology, by E. Jackson. We would remind our readers that it is the June number which contains Dr. Clark's valuable summary of the literature of cancer for the preceding year.

Surgery of the Blood Vessels. By J. Shelton Horsley, M.D., F.A.C.S., Surgeon-in-charge of St. Elizabeth's Hospital, Richmond, Va.; a Founder and Fellow of the American College of Surgeons; Ex-President of the Richmond Academy of Medicine and Surgery; Member of Southern Surgical and Gynecological Association, etc. Octavo of 308 pages, with 89 illustrations. Price, $4.00. St. Louis: C. V. Mosby Company, 1915.

This is a monograph of much more than ordinary importance and interest. The value of Horsley's original work directed to the perfection of technique in the surgery of the blood vessels, especially of end-to-end suture of artery and vein, is too well known to require more than passing mention here. In this monograph, chapters are devoted to the structure and histological repair of blood vessels, the history of blood-vessel surgery, the indications for and technique of blood-vessel suturing, transfusion, hemorrhage, thrombosis and embolism, aneurysms, and several other subjects more or less germane to the title. The crowning feature of the book lies in the setting forth of the author's own ideas and the descriptions of his own work. As would be expected and desired, we find an extended exposition, with adequate illustrations of his present technique; but we also find concise descriptions of, or references to, nearly all the principal methods of blood-vessel anastomosis and transfusion originated by other surgeons and laboratory workers. In view of the general excellence and completeness of Horsley's survey of this field, it seems unfortunate that the presentation of his manuscript for publication could not have been delayed a few weeks; for then the description and discussion of the Lewisohn-Weil citrate method of indirect transfusion, which bids fair to supersede most if not all former methods, undoubtedly would have been included. Horsley's preface is dated January, 1915. Lewisohn's preliminary note on the citrate method of transfusion appeared in the Medical Record, January 23, 1915, and Weil's in the *Journal of the American Medical Association*, January 30; while in a still later communication (*Surgery, Gynecology and Obstetrics*, July, 1915) Lewisohn calls attention to its many apparent advantages over the older methods and details a sufficient number of case reports to impress one with its safety as well as its greater ease and simplicity of application.

Not only those who may be called upon to do blood-vessel surgery and transfusion but also the general practitioner, who should be cognizant of the indications for their use, their value, and their limitations, will find both pleasure and profit in a careful study of this monograph.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-fifth Annual Meeting held at Philadelphia, September 20-25, 1915.

SECTION ON MEDICINE.

First Day—Tuesday, September 21.

Clinical Findings of Foreign Body in Air Passages of Children.—Dr. HENRY T. PRICE of Pittsburgh believed that the accident of foreign bodies being drawn into the respiratory tract was not sufficiently considered and that too much stress was placed upon Nature's ability to remove such offending substance. Reference was made to the possibility of relief given by the endoscopist and to the following points in diagnosis given by Dr. Jackson: (1) History; (2) indirect examination of the larynx; examination of the throat and nasopharynx; (3) radiography; (4) physical examination by an internest; (5) endoscopy. Physical findings he classed as: (1) Immediate effect of operation; (2) secondary effect; (3) remote effect, when the development of gross pathological lesions had eliminated all thought of foreign bodies. History was the most important element in diagnosis; radiography, invaluable. If the presence of the foreign body were overlooked a mistaken diagnosis might readily be made of laryngitis, diphtheritic croup, pertussis, asthma, laryngismus stridulus, or edema of the larynx. So-called tuberculosis, bronchiectasis, abscess, empyema and pneumothorax were mentioned as remote effects of foreign body in the lung. So definite were these conditions, apparently, that the possibility of their being secondary to a foreign body was not usually considered.

Dr. CHEVALIER JACKSON of Pittsburgh emphasized the importance of the physical signs of foreign body in the air passages. A radiograph should be taken in every case. There were many cases in which the history of a foreign body accident had been ridiculed or ignored by the practitioner first seeing the patient. It was possible that a foreign body might be in the lung without causing symptoms for a number of weeks before the insidious onset of vague symptoms occurred. While many cases of supposed or actual bronchiectasis, "tuberculosis," pulmonary abscess had been due to foreign body this seemed to be the last possibility suggested to the mind of the practitoner. The mortality of removal of the body by bronchoscopy through the mouth was so slight that when the diagnostic methods stated by Dr. Price left the matter in doubt, a diagnostic bronchoscopy should be done.

Dr. GEORGE C. JOHNSTON of Pittsburgh referred to a case which had come into the hands of Dr. Jackson of a young man in whom tuberculosis had been diagnosed and who had been ill since a child. Upon removal from the lung by Dr. Jackson of a form of paper clip long, long since passed out of use, the patient recovered.

Dr. PRICE, in closing, emphasized the importance of operation without anesthesia.

Pyelitis in Infancy and Childhood.—Dr. FRED E. ROSS of Erie defined this condition as an acute infection of the urinary tract which might become chronic and almost always protracted. Its apparent infrequency he attributed to its non-recognition. The infecting organism was most often the colon bacillus. While the route of infection was not known in all cases, the direct route from the ascending colon to the right kidney by way of a chain of lymphatics was suggested. Diagnosis rested upon microscopical examination of the centrifugalized sediment of urine or upon a series of such examinations. While most cases were uninfluenced by treatment he used either alkaline diuretics to render the urine alkaline, or preferably large doses of hexamethylenamine. A study of twelve cases was given. The youngest patient was three months of age; the oldest seven years. Four patients had chills with cyanosis and fever. Albumen was found in the urine in 50 per cent. of the cases. The method used for collecting the urine was the use of a wide-mouthed tablet bottle and adhesive plaster.

Dr. GEORGE E. HOLTZAPPLE of York said that the condition should be borne in mind in children with irregular, obscure fever, general debility with pallor, loss of appetite and gastrointestinal disturbances. Pain in pyelitis might simulate appendicitis and he had seen such a case brought for operation. He regarded it as of paramount importance to discover the pyuria and determine the nature of the infection. The pediatrist should be alert lest a possible case of the condition might be overlooked.

Dr. J. P. CROZER GRIFFITH believed that in every case of an infant with irregular temperature in which the cause was not absolutely clear the urine should be examined. He had had four or five such cases under his care at one time.

The Treatment of Tuberculous Peritonitis; Medical vs. Surgical.—Dr. THEODORE J. ELTERICH of Pittsburgh said that although Koenig had proposed laparotomy for tuberculous peritonitis this operation had not been shown to have a specific influence in increasing resistance to the tubercle bacillus. He mentioned the greater danger in tapping for tuberculous peritonitis than in the same operation for ascites of the pleural cavity. Medical treatment consisted in hygienic, dietetic, local and internal therapeutic measures. Green soap was used locally thickly spread upon the abdomen, allowed to remain for fifteen minutes and washed off, applications being made every other day. Thiocol was given in doses of four to seven grains three times daily and the treatment continued until the ascites had disappeared. Later cod liver oil and iron were given. Whenever possible the patient was sent to seashore, mountains, or country.

Morbidity and Mortality from Certain Communicable Diseases of Childhood as Influenced by Public Health Control.—Dr. B. FRANKLIN ROYER of Harrisburg said that the only true index of the communicable diseases of childhood was the death rate. From a total of 24,471 cases of typhoid fever in 1906 the number of cases had declined to 7,547 in 1914. Measures influencing the incidence of typhoid fever he said had an even greater effect upon the mortality of diarrhea and enteritis. Deaths from measles and diphtheria had shown a general decline under public health measures, and those from whooping cough had been cut in half. Scarlet fever had not shown the same tendency to decline and the best results might not be hoped for in this disease until more was known of its etiology and communicability.

Intramuscular Injections of Antitoxin.—Dr. SAMUEL S. WOODY of Philadelphia said it had been definitely proven that the intramuscular injection of diphtheria antitoxin had many of the advantages of the intravenous method and many points of superiority over the subcutaneous injection. Advantages over the subcutaneous were more rapid absorption; quicker therapeutic action; the smaller dose needed for the same effect; less pain; less liability to subsequent abscess. The author's technique was: Injection in middle of outer aspect of thigh. The skin received two coats of 5 per cent. tincture of iodine and the needle was plunged well into the muscle. The skin was then sponged with alcohol and a sterile gauze pad or collodion dressing was applied. The antitoxin was of a concentration of 1,100 to 2,000 units per cubic centimeter and the majority of cases received but one initial dose. In a series of 600 cases the initial dose varied from 3,300 to 100,000 units and rarely had a second dose been necessary. Excluding bronchopneumonia and brain abscess there was a mortality in the 600 cases of three per cent. due to the action of the toxin.

Dr. THEODORE LEBOUTILIER of Philadelphia confirmed the statement of more rapid absorption and prompt results obtained by the intramuscular injection than the subcutaneous. A reduction of the dose to one-half gave better results also by the intramuscular method. He believed the intravenous injection would be the coming method of administration of antitoxin. It was absolutely painless and a further reduction of the amount of antitoxin was also possible.

The Practical Value of the Schick Toxin Reaction in Diphtheria.—Dr. JOHN A. KOLMER of Philadelphia described the mechanism of the Schick toxin reaction and gave the result of his investigation upon true and pseudoreaction. The practical value of toxin reaction in the diagnosis of diphtheria was shown. The detection of the susceptibility to diphtheria was mentioned as a guide in the administration of antitoxin for prophylactic and therapeutic purposes. A demonstration of the Schick method was given.

The Results of the Examination of Cultures from Suspected Cases of Diphtheria and Other Pharyngeal and Nasal Conditions.—Dr. GEORGE REILY MOFFITT of

Harrisburg gave his results in 3,732 examinations of blood serum cultures from throat and nose infections and of smear preparations of swabs from 100 of the cases made in the last six years in his work in the health boards of Harrisburg and Steelton and for the Harrisburg High School Board, with the following conclusions: (1) Diphtheria cannot be diagnosed in its early stages without the assistance of the laboratory. (2) In negative reports on examinations for diagnosis subsequent cultures should be taken in suspicious cases. (3) Throats of patients having had diphtheria are not free from the bacteria at any given time after the onset of the infection. (4) Negative cultures should be found before quarantine for diphtheria is removed. (5) When diphtheria bacilli persist in a throat after disappearance of all other manifestations of disease they may often be readily eliminated by using buttermilk as a gargle. (6) Virulent diphtheria bacilli may be present in a nose or throat without causing any symptoms in the host though capable of causing the disease in contacts. (7) Membraneous laryngitis or croup may be caused by the pneumococcus and such infection may prove fatal.

The Heart of the Athlete: Its Prospect and Protection. Dr. Robert N. Willson of Philadelphia said that two vital questions involved in college and schoolboy competitive athletics were: (1) The ultimate (post-graduation) result of public competitive athletics upon the health and lives of the participants; (2) the possibility of determining the genuine physical integrity of the proposed participant or his lack of the same, especially with respect to his heart. Reference was made to the many deaths in recent years among former athletes. He knew of no instance of recovery from a major infectious disease in an athlete, except in the typhoid epidemic at Easton, where a number of undergraduates—probably not then shorn of their resisting forces—had made a successful fight and recovered. It was to be remembered that the normal heart would not tolerate repeated insults without loss of recuperative power. Latent athletic injuries would seem to explain the tendency of the strong and robust to die when the less powerful won out against infectious disease. A still more radical evil was the encouragement offered by college and university to the schoolboy to emulate his college brother in competitive athletics. Dr. Willson said that he stopped short of advising against active competition as the Germans had but pointed rather to signboards written in bold letters. Trainers should be taught the meaning of the collapse of to-day in the future of the athlete. He believed that some day college authorities must of necessity conclude that no form of athletic event was sane which demanded of the participants the semiconscious state of heart exhaustion at its conclusion.

Dr. N. A. Stauffer of Philadelphia believed in competitive sports for the same reason that he favored competition in other professions. He referred to the fact that all of the University of Pennsylvania football team were in excellent health and observed that records of athletes compiled by other authors did not bear out Dr. Willson's statement that competitve sports were harmful, except in the unprepared.

Dr. Albert E. Roussel said that all physicians should appreciate the value of graduated exercise throughout the greater portion of life; the exercise, however, should be in selected cases and under supervision.

Dr. Judson Daland of Philadelphia suggested that the late results in athletes apparently due to excessive work might be due to excesses in alcohol, tobacco, or in other directions. In changing also from an active life to a quiet one cardiovascular incompetency was much more marked.

Dr. Willson, in closing, stated that he was not opposed to competitive athletics if they could be rendered sane. The point he had raised was the action of the athlete's heart in the presence of systemic, especially, infectious disease. He believed it time to safeguard the hearts, vessels, and lives of the school and college boys.

Second Day—Wednesday, September 22.

Some Criteria Underlying Prognosis in Certain Forms of Cardiac Insufficiency.—Dr. James E. Talley of Philadelphia said that the average patient of middle life with symptoms suggesting beginning cardiac insufficiency would probably have either (1) Primary chronic, endo-, and myocardial disease, usually rheumatic; (2) primary endo- or myocardial disease with secondary nephritis; (3) primary renal disease with a secondary myocardial and vascular disease; (4) primary arterial or arteriocapillary sclerosis with secondary cardiac and renal disease; (5) syphilitic cardiovascular disease. Groups 2, 3, and 4 were groups of special interest because of their frequency, association with pathological elevation of blood pressure, and because their study had tended away from the conception of renal disease being solely responsible for hypertension and toward the renewal of the old conception of primary arteriolar-capillary fibrosis. Reference was made to the study of these cases by Janeway and Stengel. The underlying criteria in prognosis were to be found in symptoms and objective signs. Periodic early morning headache meant a uremic death for a large number and an apoplectic death for a somewhat less number. Although all three groups were doomed, the one with the vastly impaired elimination would have a renal death, and probably earlier than the other two.

Dr. Joseph Sailer of Philadelphia said that the differential diagnosis here was in degree rather than in kind and that in such diagnosis Dr. Talley had most properly laid stress upon blood pressure, colorimetric tests of the functional capacity of the kidneys and the graphic methods of recording the action of the heart. These methods, however, were not absolute. The increase or decrease in the functional capacity of the kidneys, the rise or fall of arterial tension, and possibly the modification of the heart tracing were far more significant than any single observation.

Dr. H. B. Allyn of Philadelphia regarded the cause of the disease as of much importance in prognosis. He had seen within a few days a patient left with aortic insufficiency from scarlet fever when three years old who was now approaching fifty and whose heart for the last fifteen years had needed very little attention. On the other hand, in the presense of a myocardial degeneration prognosis was very much worse. Dyspnea—its degree and the readiness with which it was induced—was often of more value in prognosis than any physical sign.

Dr. H. A. Hare of Philadelphia believed that the more experience one had in cardiovascular disease the more cautious one became in prognosis. While pulsus alternans was of grave import it was by no means unusual to see a patient with this symptom live for several years. In prognosis in cardiac disease the patient should be studied as a whole and not alone from examinations of the heart, even though such examinations were made with instruments of precision.

Dr. Robert N. Willson of Philadelphia remarked upon the difficulty of determining the degree of muscular cardiac disease in a given case. The tests so vaunted were to his mind of little value, and many a heart tested in the office and pronounced sound was not competent.

Dr. James M. Anders of Philadelphia remarked that the most satisfactory method of determining a prognosis was to observe the patient for a given time, which privilege should always be requested.

The Electrocardiogram; Its Value as an Aid in Diagnosis.—Drs. James D. Heard, F. B. Utley, and A. P. D'Zmura of Pittsburgh presented this paper, which was read by Dr. Heard. It was stated that the electrocardiograph was capable of furnishing information upon the site of origin of the excitation wave, its subsequent course of propagation through the conducting system and the heart muscles, the existing preponderance of one cavity over another, the method of drug action and the indications for its use and discontinuance; definite evidence regarding certain disturbances of mechanism based upon galvanometric curves was at present accepted as final. The importance of regarding a given patient from the standpoint of disturbance of cardiac mechanism rather than from valve lesion or "myocarditis" was shown. With the exception of the pulsus alternans the electrocardiograph was shown to be the instrument of choice in diagnosing disturbances of cardiac mechanism. Illustrative plates, prints and tracings were exhibited.

Dr. Edward B. Krumbhaar of Philadelphia said that as the best demonstrator of the type of arrhythmia the electrocardiograph had unquestionably proved its clinical value. Auricular flutter could be determined only by this method. It was hoped that it might also be of value in the study of the functional capacity of the diseased heart muscle. He felt that if the attention of the clinician could be diverted from the valvular murmur and focused upon the actual state of the heart muscle a great advance would be made in treatment. Upon these

lines the electrocardiograph had already shown the hitherto unknown existence of defects in individual branches of the bundle of His.

The Significance of Cardiac Pain.—Dr. DAVID RIESMAN of Philadelphia classed the causes of pain in the region of the heart as cardiac and extracardiac. Among the latter dyspepsia, herpes zoster, pleurisy, and pleurodynia were the most common. Of the cardiac causes myocardial weakness was of great practical importance as it might be overlooked because murmurs were often absent. Additional causes of cardiac pain were angina pectoris and aortitis. Reference was made to pseudoangina pectoris and to the question whether the term should or should not be employed.

Dr. LAWRENCE LITCHFIELD of Pittsburgh said that of two cases of which he had knowledge one had been attended by the best men in the country and had died from an anginoid attack without ever having been told that the cardiac pain was grave. The other case was of the type presenting pain in both arms. The cardiac disease was not regarded as serious, but the man had died within a month in an anginoid attack.

Dr. JAMES E. TALLEY of Philadelphia remarked, apropos of the cases cited by Dr. Litchfield, that in cases in which angina pectoris was suspected, the less found wrong with the heart upon examination, the more certain might one be of the diagnosis. In a series of 500 cardiovascular and cardiorenal cases there were thirty-five cases of genuine angina pectoris. One-third had succumbed to an acute anginal attack, and two-thirds to gradual cardiac death.

Dr. SOLOMON SOLIS-COHEN of Philadelphia called attention to the importance of syphilitic aortitis and so-called pseudoangina in that syphilitic aortitis was often mistaken for angina, the syphilitic nature of the condition overlooked, and the patient, therefore, allowed to get into a much worse state than he otherwise might. Dr. Cohen had observed many cases of so-called pseudoangina in which the pain occurred without structural lesions in the myocardium coronary arteries, or the aorta, in which upon proper recognition and treatment the pain had disappeared and the patient live, as in one case under his observation at the time, for more than twenty-five years.

Dr. ROBERT N. WILLSON of Philadelphia said there were two distinct types of true cardiac pain,—the dull heavy pain of distention and dilatation, and the sharp cutting pain of aortic valve and aortic disease. He regarded as questionable whether angina might be properly included under cardiac pain; certainly such right had not been demonstrated. He believed there was no such entity as pseudoangina pectoris. The cardiac nervous mechanism, including the ganglia of the auricles and of the coronary sinus under the influence of nicotine, showed definite signs of disease, and here he believed eventually would be found the real seat of angina. Should this be so, it would again be permissible to speak of angina as cardiac pain.

Dr. RIESMAN in closing said that by cardiac pain he meant pain in the cardiac region. The crux of the matter was involved in the question whether angina pectoris was a disease, or a symptom. To be borne in mind was the fact that there could be very sharp pains paroxysmal in character that were not associated with the dread prognosis acompanying the disease called angina pectoris.

Treatment of Myocarditis.—Dr. JAMES M. ANDERS of Philadelphia considered the treatment of acute myocarditis due to the acute infections including rheumatism and rarely syphilis. When antirheumatic measures were indicated the heart was to be carefully guarded by stimulants and modification of this treatment might be necessary because of cardiac weakness. Digitalis was warned against when the myocardium was the seat of an acute inflammatory degeneration. In all forms of severe acute myocarditis prolonged absolute rest was enjoined. In chronic myocarditis the exclusion of chronic valvulitis was exceedingly difficult in the presence of murmurs. In the stage of compensation exercise must not be such that would tax the reserve force. In chronic myocarditis due to lues salvarsan should not be administered intravenously. In diet a low protein content was indicated with a minimum of flesh foods, strong stock soups, and legumes and an elimination of all articles causing intestinal fermentation. Suitable changes of air were beneficial, as were also carbonated baths in appropriate cases. In the stage of insufficiency, physical and mental rest were imperative and in some cases cardiac stimulants were necessary. The untoward effect of prolonged rest might be minimized by resistance exercises. Digitalis, if administered, should be given cautiously combined with an arterial relaxant. In decided failure of compensation Dr. Anders had found most useful strychnine, gr. 1/40; caffeine citrate, gr. 1; spartein sulphate, gr. 1/4. Venesection was possibly useful in excessive hypertension in threatened apoplexy. Saline purgatives were advised. In diet the digestible proteins were freely allowed, with the exception of those rich in purin bases. The fluid intake should be lesseneed, especially in the presence of edema.

Dr. DAVID RIESMAN of Philadelphia observed that the term myocarditis was rather loosely used when applied to acute diseases. Chronic myocarditis was never a single process. Functional and structural changes in the vessels, lymphatics, arterioles, and viscera were to be studied from the functional and anatomical standpoints. In the treatment of acute myocardial degeneration the essential point was that of food. When milk was given as the sole diet milk sugar should be added. The patient's life with its activities was to be adapted to the capacity of the heart as nearly as could be determined, for such capacity, unfortunately there was no definite test. With compensation lost rest and digitalis were the main remedies.

Inadequacy of Ordinary Methods of Disinfecting Typhoid Stools.—Dr. EDGAR M. GREEN of Easton in this paper said that reports from about thirty hospitals throughout the State showed that most of the institutions were disinfecting stools with chloride of lime, carbolic acid, or some of the composite commercial disinfectants with a varying period of time from a few minutes to an indefinite time. Pathological experiments showed such disinfection was useless. Steam sterilization which could be made complete in a typhoid stool in from 20 to 30 minutes was strongly advised in all hospitals. In private practice where steam was not available the well broken up stool should be exposed to a 6 per cent. solution of commercial formaldehyde for at least two hours, or treated with a cupful of commercial unslaked lime and hot water.

Dr. B. FRANKLYN ROYER of Harrisburg agreed with Dr. Green that hospitals should use steam in the disinfection of stools and urged that nurses in training be thoroughly taught effective methods of the disinfection.

Some Remarks with Regard to Hemoptysis in Pulmonary Tuberculosis and Its Treatment.—Dr. ELMER H. FUNK of Philadelphia restricted the term hemoptysis to the expectoration of blood with its origin below the glottis and said that by far the most frequent cause of hemoptysis so considered was tuberculous infection. The possible association of other causative conditions was, however, to be borne in mind. Among 373 patients in the department for diseases of the chest of the Jefferson Hospital with advanced pulmonary tuberculosis hemoptysis was present in 164, or 44 per cent. In 167 patients treated to the end the symptom was noted in 90 instances, 54 per cent. While hemoptysis was most frequent in young adult life there had been reported the death of an infant of three months from hemoptysis due to pulmonary tuberculosis and other cases had been collected in young children. While the average adult patient died within four years after the first hemorrhage, Goethe had had a profuse hemorrhage at nineteen and another at eighty-two; Rousseau had one at twenty-three and lived to the age of sixty-six. It had been the experience of the author that the extent of the lesion did not bear a direct relation to the occurrence of hemorrhage; it might be the first or the last symptom of the disease. In the studies carried out at the Jefferson Hospital pulmonary hemorrhage had been grouped under: (1) Frank profuse hemorrhage; (2) small and mild hemorrhage; (3) persisting hemorrhages; (4) blood streaked sputum. It was advised that the expectoration of blood streaked sputum be given as careful thought as the profuse frank hemorrhage. Reference was made to what might be called an epidemic of blood spitting in a group of consumptives and to a series of observations being made in such connection. In the treatment of hemoptysis in pulmonary tuberculosis individualization was said to be the keynote of success. Rest was by far the most important therapeutic procedure. Dr. Funk was inclined to the belief that emetine was of distinct value in hemoptysis in which there was a tendency to repeated small hemorrhages or in cases suggesting capillary bleeding. The time-honored ice bag to the chest had been disregarded. Persistent bleeding called for a consideration of therapeutic artificial pneumo-

thorax. Of vital importance was the free daily movement of the bowels, in the absence of positive contraindications.

Dr. C. R. PHILLIPS of Harrisburg reported their observations at State Tuberculosis Dispensary No. 13 from March 1, 1908, to March 1, 1915, covering a series of 5,700 cases diagnosed as tuberculosis pulmonalis, in which they had concluded that: about as many people died from tuberculosis without having had hemorrhage as those who had, hemorrhages were as likely to occur early in the disease as late; dispensaries and sanatoria reduced the frequency of hemorrhage. In only 21 per cent. did hemorrhage occur after having come under their care. Hemorrhage *per se* could not be considered; it was but a part of a vast clinical and pathological picture, the significance of which depended upon the accompanying conditions.

The Use of Tuberculin and Other Bacterial Products (Bacterins, Vaccines, etc.) by the Mouth.—Dr. SOLOMON SOLIS-COHEN of Philadelphia reported the results of five years' personal observations, chiefly with tuberculin; also with preparations of pneumococci, staphylococci, and streptococci. The bacterial preparation was given in about one ounce of physiological salt solution or diluted beef juice with the stomach empty; repeated according to the effect, usually in ascending doses, every third to seventh day. With tuberculin, special and careful management was necessary to avoid toxic reaction. While the method of administration did not confer power upon the vaccine to do that which vaccines could not do under any circumstances, it was in most cases of equal efficacy with the subcutaneous injection. Digestion was not disturbed.

Dr. JOHN A. RODDY of Philadelphia said that the results of studies at the Jefferson Hospital gave evidence of reaction from administration by the mouth of the following strains of killed bacteria. Staphylococci, streptococci, pneumococci, and the bacillus of Friedlander. These evidence lymphocytosis or leucocytosis; pronounced typical vaccine reaction from overdoses; decided clinical improvement, amounting in about one-half the cases to complete clinical recovery. In the majority of patients so treated after other methods had failed there was some improvement. While the group of cases was too small from which to draw sweeping conclusions it was fair to believe that the method showed distinct clinical efficacy and was worthy of further investigation.

Third Day—Thursday, September 23.

Observations on Thyroid Therapy. — Dr. WILLIAM HARMAR GOOD of Philadelphia from a study of the chaotic condition of thyroid therapy concluded that the average dose, 4 grains, of thyroid recommended by the U. S. Pharmacopeia, was very dangerously excessive, especially in myxedema, where its indication was most clear. He believed that 1 or, at the most, 2 grains, might be considered a safe average dose. The improper and confusing term, thyroid extract, he believed should be disregarded for glandulæ thyroidæ sicca, which was the proper term.

Chronic Arthritis.—Dr. THOMAS MCCRAE of Philadelphia drew attention to an infection as the etiological factor in the great majority of cases of chronic arthritis. This knowledge was of especial importance in view of the often progressive form of the condition. The application of the etiological therapy should be distinguished from measures merely symptomatic or those directed to improve the condition of the joints already damaged.

Dr. A. B. HIRSH of Philadelphia said that the terms, "rheumatoid arthritis" and "chronic rheumatism" should be named only to be discarded. A tenetative nosology, he said, was now possible for chronic arthritic disease, based upon the researches of Dr. McCrae and others in this field. Three factors involved in the definite treatment method of one group of joint infections, wrongly classed, "deforming arthritis" were (1) removal of the source of infection; (2) persistent local applications over each affected joint until all possible removal deposit was gone; (3) a systematic effort to correct the patient's general metabolism. An exhaustive differential treatment was essential; the most efficient local treatment was the high pressure, small volume, and low frequency static wave current sent through 22-gauge flexible metal plates closely fitting the involved joints.

The Tertiary Manifestations of Syphilis as Seen in a General Medical Ward.—Dr. JOHN H. MUSSER, JR., of Philadelphia based this study upon the results of the Wassermann test made in every case of chronic disease in the men's medical service at the Presbyterian Hospital in the last four months, excluding frank pneumonia, typhoid fever cases, and necessarily those dying or leaving before the test could be made. One-fifth of the patients with chronic disease had syphilis. Cases were reported showing the diverse forms assumed by the disease. While the therapeutic results were good they could scarcely be called brilliant. The author concluded that a large percentage of cases of chronic disease was dependent upon syphilitic infection; that it was impossible always to detect such infection without the Wassermann reaction; and, that because of the importance of diagnosis of such cases a Wassermann test of the blood serum should be made in every case of chronic disease admitted to the general medical ward.

Dr. JOSEPH SAILER of Philadelphia, in illustration of the frequently unusual manifestation of syphilitic infection, cited two cases, both in physicians. One suffered merely from malnutrition and indefinite digestive disturbance for which there was no adequate explanation. In this case the Wassermann was positive. Two weeks following the first injection of salvarsan the man had gained ten pounds and had since remained well. The other patient suffered merely from an irritative dry cough of the most persistent character. He was the father of three healthy children. There were present none of the ordinary manifestations of syphilis. A positive Wassermann suggested the use of salvarsan and the cough stopped almost immediately after the first intravenous injection. The author assumed from laboratory reports that at least 9,000,000 people in the United States were suffering from this disease and thought it fair to conclude that in the majority of this number the manifestations were so obscure that there was no suspicion of its existence.

The Influence of Low and High Protein Intake upon the Excretion of the Acetone Bodies in the Urine in Diabetes Mellitus.—Dr. JACOB ROSENBLOOM of Pittsburgh from a study of five cases of diabetes found that the amount of protein fed played an important rôle in the excretion of the acetone bodies in the urine. From experimental data the conclusion was drawn that this increased excretion was due to the presence in the protein molecule of certain amino acids that were ketogenetic. It was suggested that the selection of proteins poor in amino acids might control the excretion of the acetone bodies in diabetes mellitus.

Dr. C. L. PALMER of Pittsburgh emphasized the point that certain constituents of ordinary protein food, such as meat, had a ketogenetic influence by the separation of the NH_2 group from their amino acids and expressed the hope that Dr. Rosenbloom and other biological chemists would continue the search into the intricate phenomena of diabetes mellitus.

NEW YORK NEUROLOGICAL SOCIETY.

Three Hundred and Thirty-ninth Regular Meeting Held Tuesday, April 6, 1915.

Dr. WILLIAM M. LESZYNSKY, PRESIDING.

Tuberculous Meningoependymitis with Dilatation of Cavum Septi Pellucidi. — Dr. FREDERICK TILNEY presented this case. The patient, a fifteen months infant, had a perfectly characteristic tubercular meningitis. An interesting fact in the case, however, was that the child suffered from right hemiplegia the last three weeks before death. This warranted the belief that possibly there might be some degeneration of the Wallerian type, but no evidence was found of secondary degeneration in the motor area. The pathology of the condition showed a typical state of basal meningitis with miliary tubercles. The septum lucidum was filled with thick gelatinous substance. There was present a sinistral version. The brain itself presented no changes except in the region of the ventricles where there was tubercle formation giving characteristic tubercular ependymitis. The space was thickened between the two layers of the septum which was a dilated sac, containing a gelatinous mass. There were also small hemorrhages in the folia of the right cerebellum. Dilatation of the foramena on both sides was noticeable (in the specimen) as well as that of the lateral ventricles and interior walls. Dr. Tilney said that the sinistral version depended upon which of the nerves was most involved. Further study would have to be given to the case. As to the formation of gelatinous material in the fifth ventricle, there was, under normal conditions, a

little fluid, and therefore this fluid was an exudate from the inflammatory process into the Septi. The child had died the previous December and the specimen dated from that time.

Case of Tumor of the Right Occipital Lobe.—Dr. H. CLIMENKO presented this case. The patient, a male, about sixty years of age, complained of failing vision and headache. Family history: Father died of tumor of chest wall; four sisters and brother living and well; no history of new growth or diabetes. Personal history: Married thirty-nine years; six children living and well; one child died at three years with abdominal colic; one miscarriage. Gonorrhea and syphilis denied; no smoking or drinking. Past history: Patient has had diabetes for seven years; has passed small amounts of sugar, less than 1 per cent.; has had polyuria and polydipsia; has lost weight and felt weak. Present illness began two and one-half weeks ago when patient found he was doing his work improperly and found he had failing eyesight and slight frontal headache, with dizziness. His vertigo increased so that he was forced to give up work; he had difficulty in getting home, a distance of eight blocks, walking into many people on the way. One week previously, while reading, patient saw many colored animals and objects before his eyes, when the headache became more severe. He had hallucinations of myriads of rapidly moving objects and various colors. The vision was hazy. Since then the acuity of vision had been shown to have diminished. Headaches had become more severe and generalized, with increase of vertigo, coming on in attacks. The previous day vertigo was severe enough to make patient fall. The falling was not to any particular side, nor did objects rotate in any particular direction. For the past six days patient had been vomiting several times daily, the vomiting recurring with increase in headache. It was not projectile. When the headache became throbbing in character, loud splitting sounds were heard, like the stroke of a hammer on an anvil. There had been no change in smell or taste; no impairment of muscular power; no sensory symptoms other than the optic and auditory ones. The physical examination showed: Gait: no cerebellar tilt to head; no abnormality of gait or falling in either direction; station: no Rhomberg; no ataxia; scalp: no boney tenderness; eyes: at outer angle right eye echymotic spot, result of fall; pupils, react to 1 and a Wernecke's reaction to left; both halves of each retina sensitive to beam of light causing contraction of pupil at right lower portion of iris; conjunctiva moderately congested; no nystagmus; a left homonymous hemianopsia present; bilateral choked disc; veins markedly distended. Lungs: negative except for occasional râles at bases; heart: somewhat slow; pulses: Corrigan pulse; some capillary sclerosis; abdomen: reflexes diminished left side; cremasteric present and active; extremities: no diminution of muscular power on either side; no atrophy; descent of right arm more rapid than left; no ataxia; no asteriognosis; no change in pain or pressure, but faulty localization of position of left arm (patient overpoints with right hand in trying to find the left); does not overpoint with left in trying to find right; cannot mimic position of fingers of left hand with right, but can mimic positions of right hand with left; slight hypetonia of left lower extremity; descent of left more rapid than that of right; no fault in localization; knee-jerk diminished, but obtainable and equal on both sides; achilles reflex present; equal blood pressure, systolic 160; diastolic 60. February 16 visual fields showed left homonymous hemianopsia, quadrantic, about three-eighths of left halves of fields involved, entire upper quadrant and upper part of lower quadrant. Lumbar puncture showed initial pressure equal 330 mm. 5 c.c. yellow fluid removed. Exploratory craniotomy by Dr. Elsberg over occipitoparietal region; no increased tension found; no tumor found; *x*-ray examination negative; Wassermann negative in blood and spinal fluid.

Dr. ABRAHAMSON said he saw the patient when he entered Mt. Sinai Hospital. At first there was a tendency toward quadrantic vision, but later the entire half field was disturbed. The question was, were we dealing with an occipital lobe lesion or with deeper seated disease of the optic radiations? There was some disturbance of the deeper muscle sensibility. The man could not imitate very well. Localization was not very accurate. The lesion was probably deep seated and most likely parietal as well. The brain appeared normal. It was not always possible for the surgeon, on palpation, to determine whether there was not a soft glimoa involving the deeper structures. Diabetes might cause retinitis and swelling and localized softening of the brain. The history, moreover, of rather a sudden onset indicated that there had at one time been a hemorrhage which caused the exacerbation of the symptoms. The tumor was probably deep down, catching the fibers from the parietal lobes. It was more likely in the radiations than in the cuneus.

Dr. STRAUSS said he would like to call attention to two points. This man had an optic neuritis. Tumors in this region very often did not cause choked disc, although they were pretty large. A patient admitted to the service a week ago had come in in stupor and so a satisfactory examination could not be made. The examination of the brain revealed a large glioma with hemorrhages occupying the left occipital lobe, closing up the posterior horn of the lateral ventricles, but not going back into the calcarine region. It involved the optic radiation. There was no optic neuritis in that individual.

Dr. DANA said that the case might give rise to some historical reminiscences on his part as it was similar to the first case of operation for tumor of the brain ever done in this country. It was some 25 years ago, when Dr. Seguin made a diagnosis of occipital lobe tumor; Dr. Weir did the operation and found an encapsulated tumor, hard, and rather easily removed. The patient died. Dr. Dana thought, as did others, that the present case was an infiltrating glioma. One saw a good many cases with similar group of symptoms, due to thrombosis and softening, but the distinction from tumor could easily be made.

Dr. LESZYNSKY said he thought they must agree that this was a gliomatous infiltration, but not necessarily in the occipital lobe. In regard to the symptomatology of occipital lobe tumors, there might be very few symptoms. An intelligent woman of 44 years gave a history of several months' severe headache, with occasional vomiting and disturbance of vision. The headaches increased. Examination showed very slight optic neuritis, distinct homonymous hemianopsia, and vision 20/30 in each eye. No positive localization could be made at the first examination. Two and a half years before she had fallen and struck her head over the occipital region, but there were no immediate symptoms. Several months later Dr. Cushing found the symptoms had progressed, but very few sensory symptoms were present. He did a decompression and a few weeks later removed a very large tumor (endothelioma) originating in the tentorium and involving the mesial surface of the right occipital lobe. Later there was a recurrence.

Unusual Case of Multiple Sclerosis.—Dr. S. P. GOODHART showed this patient. He said the case was interesting in that its symptomatology suggested differential diagnosis between disseminated sclerosis, paralysis agitans and lenticular degeneration of the Wilson type. History of the case was as follows: The patient, a Russian Jewess, aged 29, gave a negative family history except that the father and mother were first cousins; previous to present illness her history was negative; initial symptoms occurred in her thirteenth year; there was a fine tremor of the right arm upon voluntary movement; the left arm became similarly affected a year later; headaches and pains along the spine followed in the next few years; larger excursion movements of the intention type developed later; at fifteen with subjective sensations of weakness there appeared flaccid paralysis of the left leg, followed a year later by the right. Tremor of the upper extremities then became more aggravated; fine tremor, of the Parkinson type, both in tempo and in character, as seen in paralysis agitans, appeared about five years ago; spasticity of both lower limbs developed gradually within the next few years and the same phenomenon, together with marked contractures up the upper limbs appeared somewhat later. Extreme contractures, as seen in the fingers, with the adducted and extended thumb lying flat on the palm, and the proximal phalanges of the fingers somewhat flexed, the distal phalanges extended, together with the fine tremor with the extremity quiescent, strongly suggested the P. A. position. Paroxysms of dysphagia began at the age of 26, and these attacks became so severe that when fluid was taken it would pass through the pharynx into the nose; at various times there were severe attacks of dysphagia. Speech within the last few years had become slow and measured; the voice had deepened in timbre and had a suggestive monotone; it was entirely lacking in rhythm; the facies had gradually assumed the present form; the expression was of the masked

type, due in part to the spasticity of the facial muscles; forced laughter was occasional and the mouth was at times held with the lips widely separated and the jaws apart; this position and the expression were suggestive of Wilson's disease, as seen in one case. On attempts at speech there was sometimes an involuntary effect of smiling, due probably to the automatic action of the muscles involved in this expression; on slight innervation there was a rhythmical tremor of the tongue and lips, and at times, on first attempts at speech, there was slight and occasionally an extensive tremor of the body and of the arms; on voluntary movement the tremor of the upper extremities became distinctly of the intention type; on intense emotion movements became widely extensive and irregular; there were marked flexor contractures of both upper and lower extremities. While the position of both hands and fingers were quite typical of advanced paralysis agitans, the contractures, however, were more pronounced than were found in that disease. There was nystagmus in extreme lateral position of the eyeball, varying from rotary to lateral oscillation. The position of trunk, head, general carriage, expression of face in repose and tone of voice were suggestive of Parkinson's; on active innervation of the facial muscles, however, the expression changed to that suggestive of the euphoria not uncommon in multiple sclerosis. The abdominals were occasionally present on the right side; very indistinctly elicited on the left; in spite of the contractures in the upper extremities the reflexes were not decidedly increased; Babinski and clonus and markedly increased knee jerks were present, especially on the right side; in passive movements of the arm, the rigidities showed a tendency to cogwheel interruption, far less marked, however, than in Parkinson's. In differential diagnosis, as symptoms of multiple sclerosis, there were: age and manner of inception; intention tremor; variable abdominals; slow speech; emotional symptoms; evidence of pyramidal tract involvement and nystagmus; of paralysis agitans there were: tremor while at rest; contractures; though extreme and far more than usually seen in this disease; posture and gait; the entire body moving in toto; tendency to retro and propulsion; voice and facies distinctive; of lenticular degeneration there were: the occasionally widely opened mouth; contractures; excursive movements; no emaciation and no mental deterioration; of chronic cerebellar tremor: while there was a somewhat characteristic tremor, there was no hypotonia and the presence of so many other symptoms excluded this as a diagnosis. This case emphasized what all now believed, that the pathology of all the conditions above mentioned was doubtless to be found in the midbrain and its connections. The nomenclature required a change, since what we had hitherto regarded as disease entities were really symptom complexes and all part of the same pathological process. The cerebellum, the lenticular and caudate nuclei, the paths to and from the thalami were the principle seats involved.

Dr. ABRAHAMSON said the patient had been under his observation for years at the Montefiore Home. She was almost an exact counterpart of another case, W. H., in the home for many years, and whose brain and cord were being studied by Dr. J. R. Hunt and Dr. Dunlap. The latter were described about eighteen years ago by Dr. B. Sachs under the title of multiple sclerosis and paralysis agitans in a boy. The advance reports of the findings were negative in character. The girl and the young man both showed signs of paralysis agitans, of multiple sclerosis and of Wilson's disease. It was not Wilson's disease because this was an extra pyramidal affection; this was a distinctly pyramidal tract disease; other features negatived Wilson's disease; as for multiple sclerosis, the pathological findings in the young man showed no traces of it. It resembled mostly a paralysis agitans and very likely the finer microscopical examinations would bear this out. Italian investigators sought to include the juvenile cases of Parkinson's disease with the cerebral diplegiæ; the crossed legged progression; bilateral pyramidal tract involvement, etc., in both of these cases, did certainly resemble the clinical group of Little. At present one ought to be content with a regional localization (leaving the nature of the process to be determined in the future), *i. e.* a diffuse degenerative disease of the basal ganglia and midbrain.

Dr. DANA said that the autopsy showed in the case of Willie H. that there was no degeneration of the pyramidal tracts. He thought that neurologists would have to follow the alienists for a time and use the term "allied to" in their diagnosis of these cases. The case shown here, as well as that of W. H. and some so-called cases of Wilson's disease, were in the group "allied to" paralysis agitans. Clinically they most resembled this disease, and anatomically the lesions were in the same regions. He was not so sure that the lenticular nucleus degenerations in Wilson's disease were important as the cause of the specific symptoms. The lenticular nuclei could probably be badly softened, as in gas poisoning, and the patient get well.

Dr. STRAUSS asked Dr. Dana about lenticular softening in gas poisoning. What symptoms would he ascribe to lenticular softening? Cases he had seen of gas poisoning with lenticular involvement had come to autopsy. They had never come out of coma.

Dr. DANA said that his views as to the symptoms of acute lenticular poisoning were based on certain clinical cases, and the fact that in prolonged gas poisoning there was almost always a softening of the lenticular nuclei. The cases he had seen had shown on return to consciousness mental confusion and excitement, and later motor disturbances, very much like those seen in paralysis agitans and the Wilson disease. In regard to this latter disease, he thought that perhaps too much emphasis had been placed upon the importance of the lenticular lesions than ever. In the acute gas cases there was complete recovery with probably distinct scars in each lenticular nucleus.

Dr. GOODHART said he thought there need not be symptoms with softening of the lenticular nuclei. One case that came to autopsy had no symptoms. He thought only extensive degeneration, involving the tracts passing through, would show symptoms.

Anatomical Studies Explaining Lesions Following Thrombosis of the Posterior Inferior Artery, with Lantern Slides.—Dr. M. T. BURROWS read this paper by invitation. Definite clinical symptoms frequently accompanied occlusion of the vertebral artery where it coursed over the surface of the medulla oblongata and the posterior inferior cerebellar artery, near its origin. The symptoms were indicative of lesions involving the olive, the formatio reticularis in the region of the olive, the nuclei of the IX, X and XI nerves and the longitudinal tracts passing down through the region, the restiform body and frequently the root of the V nerve. Several cases had been reported where areas of softening had not included the entire region indicated by the symptom complex. Dr. H. M. Thomas had reported cases with typical symptoms which had later cleared up and at autopsy the thrombosed vessels were found but there were no areas of softening. Injections of the separate arteries of the medulla had shown that the region in question was supplied by a number of small branches from the vertebral, the posterior inferior cerebellar artery, or both. In a large number of brains the branches were terminal branches. The posterior inferior cerebellar artery was variable both in size and position. It was, however, always present, although in some brains it might supply only a very small part of the cortex of the cerebellum. It might arise at any level from the vertebral artery. In a large percentage of the brains studied it arose at the level of the olive to supply a part of the branches to the area in question but only in a few cases did all these branches arise from this trunk. The nuclei of the VI, VII, and VIII nerves were supplied by similar lateral and terminal branches. These branches arose, however, in most brains from the middle cerebellar artery or the basilar. In a few brains these vessels might also come from the posterior cerebellar artery. The remaining portion of the medulla was supplied by vessels which anastomosed frequently with each other, with vessels of the spinal cord, and those of the opposite side. The portion of the descending root of the V nerve, substantia gelatinosa Rolando, lying at the level of the olive, might be supplied by the same vessels which supplied the penetrating arteries to the formatio reticularis, but it was frequently supplied by separate branches which coursed from below upwards or from above downwards. This was also true for the restiform body. This accounted for the frequent absence of symptoms from these parts. In a limited number of brains large anastomoses had been found between the vessels supplying the region in question, connecting the end branches of these vessels with vessels of the pons above and the spinal cord below. In a few cases these anastomoses were of sufficient size to prevent symptoms following occlusion

of these arteries at their origin from vertebral or posterior inferior cerebellar artery. In others they were smaller, so that symptoms might develop for a time from a temporary anemia of the part, later to disappear without softening as the anastomoses enlarged. The latter were frequently small and variable, as were the vessels. The branches of one vessel might intermingle with others so that penetrating arteries in the same horizontal plane had a different origin. A few of these vessels might be terminal while others had small anastomotic connections with vessels of other parts. At the instance of occlusion of these vessels symptoms indicating involvement of all of this region might be observed while later some of the symptoms might disappear and others persisting might be variable. When death occurred one would expect to find areas of softening not indicative of all the symptoms noted.

Studies of Atypical Children from the Department of Ungraded Classes.—Dr. WILLIAM B. NOYES read this paper (see Vol. 87, p. 885).

Dr. CLIMENKO said he would like to ask Dr. Noyes a few questions. The Jewish race had practised long hours of study for 2000 years, and it had not hurt them. Why restrict that now? What was a mental or psychical equivalent of chorea? He understood that chorea was an acute infectious disease; how could there be a psychic equivalent? He did not understand the report of infantilism of the uterus. How were the exact measurements obtained? In regard to Jewish mental deficiency he thought there was a peculiar psychology of the Jew. The imagination was overdeveloped in the Jewish child. It worked at the expense of the other faculties.

Dr. NEUSTAEDTER said he was connected with the Board of Health in school work both clinically and privately. Dr. Noyes was to be congratulated on the amount of ground he had covered. The society should arrange a symposium on the subject to discuss the question from the standpoint of public education.

Dr. NOYES said the point in regard to the Jewish children working after hours in a Rabbinical school was a serious one. The surroundings might be unsanitary, the child might be sick and tired out. This might be a serious menace. Sydenham's chorea might be an infectious disease, but the question raised in the paper was as to whether there might not be an accompanying mental state. The child was nervous, cried for nothing, and failed in school work, especially in attention and memory. If they could diagnose such cases they were doing good work. The case of infantilism was observed in private practice over several years. The gynecological examination was made by a competent woman physician by rectum and was accurate. Pituitary extract was used in this case without result. There were certainly distinctive features among Jewish children as among other races, but there was a similarity in defectives of all races, and they were usually lacking in imagination. The Jew was less liable to the more brutal and coarser types common to other nationalities.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Twenty-fifth Annual Meeting, Held at Atlantic City, N. J., Sept. 14, 15, and 16, 1915.

DR. JOHN W. TORBETT OF MARLIN, TEX., IN THE CHAIR.

Deep Röntgen Therapy in the Post-Operative Treatment of Carcinoma of the Breast.—Dr. GEORGE E. PFAHLER of Philadelphia read this paper. He claimed that since three-fourths of the patients with cancer of the breast came for operation only after the disease had spread from its original source and involved neighboring glands, that most of them could not expect to get well from surgery alone. Since cancerous tissue had been shown repeatedly to disappear as a result of *x*-ray treatment, even where far advanced, it could more surely be made to disappear if applied immediately after operation. The rays would help to prevent the spread of the disease, and would do much toward preventing its recurrence. At least 25 per cent. more patients could be gotten well of cancer of the breast if every patient were treated properly by the *x*-rays after operation. It was just as important to have this *x*-ray work properly done as to have the surgery properly done.

Report of Cases of Pulmonary Tuberculosis Treated by the Röntgen Ray.—Dr. J. D. GIBSON of Denver reported 757 cases of pulmonary tuberculosis which he had treated during the last fourteen years with the Röntgen ray. Of these 102 had been lost sight of, 566 were living to-day, and 91 were known to be dead. These cases consisted of 96 first stage cases, 343 second stage cases, and 318 third stage cases. Thirty of those that were reported dead had received less than two months' treatment. The author emphasized the importance of early diagnosis. Even before tubercle bacilli were found in the sputum, cases should be diagnosed by means of Röntgenograms, physical examination, and clinical history. Every case discovered in the prebacillary stage was positively curable by means of the ordinary method of treatment, with the addition of the *x*-ray and ozone. The author claimed that by this method the physicians of the United States could eliminate tuberculosis as a factor in the death rate. In other words, in ten years by applying these principles the death rate from tuberculosis could be made less than that from smallpox at the present time.

An Advance in the Treatment of Deforming Arthritis.—Dr. A. B. HIRSH of Philadelphia read this paper. He held that differentiation of varieties of the affection was of minor value for the electrotherapist, as the treatment was uniform for them all. An accurate diagnosis, to exclude other joint diseases, was a *sine qua non* for success. He divided the treatment into (1) removal of the causative center of infection; (2) improvement of the general nutrition, and (3) direct applications to each affected joint for a return, as far as possible, to normal condition. Besides static, sinusoidal and continuous currents, a corrected dietary, together with radium emanation water and with stock and autogenous vaccines, as adjuncts, were indicated. When faithfully carried out, these would lead, as a rule, to removal of the disease.

Report of Progress in the Fulguration of Malignant Growths.—Dr. WORTHINGTON S. RUSSELL of New York spoke of the work at the New York Skin and Cancer Hospital in the treatment of malignant growths by the de Keating Hart method of fulguration, and showed numerous lantern slides illustrating the results obtained. Since 1912 they had treated about 400 cases of cancer of all stages. As yet they were not in a position to draw positive conclusions.

The Physical Treatment of Reflex Disturbances.—Dr. FRED H. MORSE of Boston read this paper. He said there were many reflex conditions, like headache, backache, in fact, pains in various parts of the body, hysteria, temporary mental derangements, that were due to functionally disturbed or acutely diseased conditions of some of the organs which were of consequence enough to require special treatment independent of the underlying cause, which in the majority of instances was intestinal stasis. Also after the cause was apparently or really removed these reflex symptoms continue indefinitely, which was an inducement for patients to take sedative drugs, patent medicines, etc. While due respect was given to the various physical and electrical modalities, such as could be derived from the use of the static current, high frequency, *x*-ray, vibration, etc., the galvanic current, because of its more definite action, and the fact that it could be more accurately measured, was, in the experience of the author, more efficacious in the relief of these symptoms than any other one form of physical treatment, and also because of its interpolar action, which was recognized as having a direct nutritional effect in the deeper tissues. Authorities were quoted to substantiate the idea that the constant current was of much more consequence in the treatment of disease than had been accredited to it in recent years, and he hoped to see a revival of interest in it in the future.

Hyperthyroidism and Its Treatment.—Dr. WILLIAM BENHAM SNOW of New York read a paper on this subject. He said the method employed was the combined use of the static wave current, *x*-ray, and mechanical vibration. The electrical current reduced the gland by forcing out accumulated colloid and effete matter. The *x*-ray effectively inhibited or lessened the excessive secretion of the thyroid gland, the disturbing factor. Mechanical vibration applied over the proper intervertebral spaces aided by contracting the arteries, thereby to a degree diminishing the excess secretion. Dr. Snow claimed for the method uniform success, even in extreme cases, without danger or inconvenience to the patient. The disturbing heart symptoms were permanently corrected; there was a return to health, with

prompt increase in body weight; and the ophthalmic symptoms improved under the combined method.

The Utility of the Static Machine.—Dr. HERBERT F. PITCHER of Haverhill, Mass., in this paper made a plea for the intelligent use of the static machine. The well meaning physician who lays aside a good static machine lost one of the most valuable therapeutic agents in existence. No instrument required more study and knowledge, and there was none which would give richer returns when employed in a scientific manner. The author emphasized the importance of keeping the machine dry and clean.

Different Forms of Neuritis and Their Treatment.—Dr. MARY ARNOLD SNOW of New York said the treatment depended wholly on the pathological condition presented and the case. Drug therapy was usually but palliative. The physical modalities included dry hot air, radiant light and heat, the static wave current, static sparks, the static brush discharge, the de Kraft blue pencil brush discharge, d'Arsonvalization, the static resonator effleuve, the Oudin current, mechanical vibration, and the *x*-ray, each having its respective place in the relief and cure of neuritis.

The Treatment of Headache.—Dr. FREDERIC DE KRAFT of New York, after reciting the various causes of headache, called especial attention to the uses of electricity in the treatment of toxic headache. By the use of the high frequency current the blood could be heated to such a degree that the smaller blood-vessels in the skin and mucous membranes became widely dilated. As a result of this rush of large volumes of blood to the periphery for cooling effect, relief of venous engorgement in internal organs was effected. Renewed activity occurred resulting in an improvement of elimination. Dr. de Kraft also called attention to the mechanical effects of the static wave current, the static induced and the sinusoidal current. When employed with large electrodes over the abdomen and over the dorsal and lumbar region these modalities might be depended upon in restoring the tone of both voluntary and involuntary muscular fiber. This would bring about improved vascular tone and removal of venous stasis in the splanchnic area. As a result of the improvement in the activity of the organs of elimination greater freedom from toxic elements in the blood was secured. He also called attention to the general oxidizing and pain relieving effects of the static brush discharge. A judicious combination of the use of these electrical modalities, together with exercise in the open air and regulation of the diet to suit the needs of the system, would result in the removal of periodical toxic headache in a very large number of cases.

Dilatations of the Aorta.—Dr. A. W. YALE of Philadelphia, in this paper discussed the pathology of dilatations of the aorta, the importance of the use of the fluoroscope as an aid in diagnosis, and the sphygmomanometer readings. He advocated treatment with the static condensed current followed by vibration of the seventh cervical interspace, and reported cases treated by this method.

Diathermic Treatment of Thrombo-Angeitis Obliterans.—Dr. WILLIAM T. JOHNSON of Philadelphia said that this was a thrombotic process, which occurred in both arteries and veins, usually in the lower extremities, probably caused by some microbial agent. The failure in nutrition went on to gangrene, and amputation became imperative. The treatment consisted in applying the high frequency current by the diathermic method, one suitable electrode being placed over the toes, which were properly protected, and the other on the limb at a point above the manifestations of the disease. Great care must be taken to avoid burning. The current strength was largely determined by the sensations of the patient, although it was best not to exceed 500 milliamperes. Daily treatments should be given.

Report of a Case of Polyneuritis of Motor Type.—Dr. WILLIAM MARTIN of Atlantic City reported this case. The etiological factor in the case was of a virulent toxic type, at the time thought to be uremic, occurring at mid-term of pregnancy. Evacuation of the uterus stopped the seizure, but left the patient with a practical paralysis of the voluntary muscles and some of the organic functions. Loss of motion and sensation in legs was complete. Treatment was by the use of the static wave over the spine, sinusoidal and interrupted constant current, alternated, in labile manner, applied to affected parts. Spinal vibration and vibration to motor points were added to the above. The patient made a complete recovery.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MASSACHUSETTS STATE BOARD OF REGISTRATION IN MEDICINE.

September, 1914.

(*Concluded from page* 726.)

DIAGNOSIS AND THERAPEUTICS.

1. Mention three of the most frequent complications which may arise during an attack of lobar pneumonia. Give treatment for one of them.
2. What complications may arise in whooping-cough? What means should be adopted in the treatment of the disease to prevent them?
3. Define and give etiology of Ludwig's angina (cellulitis of the neck).
4. Give the pathognomonic symptom or symptoms, if such there be, of malaria. Also your treatment for that disease.
5. Write a page on the causes, symptoms, and treatment of exophthalmic goiter.
6. Give description, causes, and treatment of a case of urticaria.
7. Patient, a man 44 years of age, began a year ago with frequent attacks of vertigo, persistent and increasing headache, difficulty of vision and speech, convulsions without loss of consciousness, and at times nausea and vomiting. What is your diagnosis?
8. Outline a course of treatment for a case of gout.
9. Give causes, symptoms, and treatment of herpes zoster.
10. What indications or symptoms would call for the administration of ergot? If your practice does not include the use of drugs, what methods would you employ in place of the drug?

OBSTETRICS AND GYNECOLOGY.

1. Why should the blood-pressure be taken during pregnancy?
2. How should a pregnant woman be advised concerning the care of her digestive organs during pregnancy?
3. How would you diagnose a twin pregnancy at the eighth month?
4. Can you always make a differential diagnosis between uterine fibroma and pregnancy? If so, how?
5. If a hand is found presenting during labor, what should be done?
6. What would lead you to suspect a dead fetus in utero at the eighth month? What questions would you ask the parents, and what advice would you give?
7. What is the explanation of pus tubes? Assuming that the patient may not be operated on, what will probably be the future history of such a case?
8. What is the law relating to the care of the eye of a new-born child?
9. Give the etiology and treatment of icterus neonatorum.
10. How do you treat caput succedaneum?

SURGERY.

1. A woman 60 years of age, on rising in the morning, finds that her urine is distinctly bloody. She has no pain. What investigations should be made?
2. A patient has a continued fever lasting two weeks, ranging from 99 in the morning to 101.5 at night. She has two to four loose stools daily. The tongue is coated. Her abdomen is slightly tender to pressure to the left of the bladder region, and below the margin of the ribs 1 inch to the right of the right mammary line there is another tender area with slight resistance. Two years ago she had her breast removed for a so-called fibroid tumor. She has a negative Widal. She has a white count of 15,000. What would you do?
3. What are the indications for splenectomy?
4. What would you do for osteomyelitis of the tibia?
5. What is meant by artificial pneumothorax?
6. Discuss the surgical problem of abscess of the lung.
7. Describe briefly a case of abdominal fat necrosis, and state how it should be treated.
8. Give the etiology of cholelithiasis.
9. Under what circumstances may anastomosis of blood-vessels be employed?
10. A patient has round cell sarcoma of the glands of the neck. What may be done, and what is the probable history following treatment?

PEDIATRICS AND TOXICOLOGY.

1. What standards should be required of milk producers?
2. Give etiology and treatment of cholera infantum.
3. What would indicate a pyloric stenosis in early life?
4. Give your treatment for chorea.
5. What are the dangers incident to removal of tonsils and adenoids?
6. What are the different forms of congenital herniæ; what should be done in each case?
7. What is the cause of hydrocephalus? What treatment would you recommend?
8. Describe a case of toadstool poisoning and give treatment.
9. Differentiate strychnia and belladonna poisoning.
10. Describe clinically and pathologically chronic lead poisoning.

ANSWERS.

DIAGNOSIS AND THERAPEUTICS.

1. Three important complications which may occur in lobar pneumonia: Pleurisy, pericarditis, and endocarditis. *Pleurisy* may require morphine to alleviate the pain, or heat or cold, or a blister; a saline cathartic is of service; and aspiration may be indicated.

2. *Complications of whooping-cough:* Hemorrhages, bronchopneumonia, emphysema, and pleurisy. Fresh air, isolation, opiates, chloral, bromides, belladonna and quinine are among the most useful remedies. Kilmer's belt is said to be of service.

3. *Ludwig's angina* is an acute suppurative inflammation of the cellular tissue in front of the neck; it begins in the floor of the mouth, generally in the submaxillary gland. It is due to infection by the *streptococcus pyogenes*, and may follow diphtheria, scarlatina or injuries.

4. Chills, fever, and sweating constitute the typical paroxysm of malaria.

"The specific for malarial fever is quinine, which, properly given, destroys the parasites in the blood. It should be given promptly, and in the early stages in doses up to 30 grains in the twenty-four hours, and continued in doses sufficient to produce moderate singing in the ears for a week after the parasites have disappeared from the blood. The dose may then be gradually reduced, but the drug must be continued for at least three months. It may be given in capsule or in acid solution. In grave or pernicious cases it may have to be given hypodermically, to secure a prompt effect, in doses up to 10 grains thrice daily. The injection should be made into muscle, not subcutaneously. In chronic cases small doses of quinine, if plasmodia are present, are enough."—(Wheeler and Jack's *Practice of Medicine.*)

5. *Exophthalmic goiter* is a disease of unknown origin, occurring most frequently in females. Fear, fright, worry, excitement, shock, overstrain, and thyroid derangement have all been suggested as etiological factors. The *symptoms* are tachycardia, intention tremor, enlargement of the thyroid and exophthalmus. The upper eyelid is retracted, and there are other eye symptoms. Treatment consists in rest (both physical and mental), fresh air, moderate diet, absence of excitement; belladonna, bromides and other drugs have been recommended and also condemned; recently serum treatment has been advocated; surgical treatment (partial thyroidectomy, and excision of the superior ganglion of the cervical sympathetic nerve) has been recommended, and if adopted local anesthesia should be used.

6. "*Urticaria* is an inflammatory affection of the skin, characterized by the formation of evanescent whitish and pinkish elevations, attended by intense itching. It usually arises from some disturbance of the alimentary canal. Certain articles of food, such as lobsters, crabs, sausage, strawberries, etc., and certain drugs, as quinine, copaiba, cubebs, salicylic acid, etc., are prone to produce the affection. The treatment consists in the use of emetics, laxatives, and enemas to exnel the offending substances. Intestinal antiseptics should then be administered. Salol or phenacetin (gr. 5-10) may be given in subacute cases. Lotions containing carbolic acid, menthol, liquor carbonis detergens, benzoic acid, sodium carbonate, etc., may be used to relieve the itching."—(*Pocket Cyclopedia.*)

7. Cerebral tumor, or arteriosclerosis of cerebral arteries.

8. "*Treatment of gout.*—During the acute stage, the limb must be kept at rest and elevated, and hot fomentations should be applied to the joints. The diet should consist of milk and barley water, and farinaceous foods. Plain water may be freely taken, and the mineral waters have no advantage over it. Medicinal treatment should begin with a mercurial purge, and the bowels should be daily opened by a saline laxative. Colchicum wine should be given every four hours, along with citrate of potassium and hyoscyamus. It should be stopped when the pain is relieved, and if it fails morphine may be required. Laudanum or lead and opium lotion may be added to the fomentations. When the acute attack subsides, gentle friction or shampooing, and passive movements are beneficial. In *chronic gout*, careful regulation of diet, avoidance of food rich in nucleins (sweetbreads, liver, kidneys), moderation in the use of alcohol, or still better, total abstinence, and proper exercise are the principal points to remember. Arsenic, strychnine, quinine, guaiacum, and iodide of potassium may all be useful in different cases. A course of waters at a spa is valuable from the regular life that it ensures."—(Wheeler and Jack's *Practice of Medicine.*)

9. HERPES ZOSTER. *Causes.*—"The eruption and consequent neuralgic pains are the immediate result of an inflammation of the posterior ganglia of the spinal nerve roots; but the cause producing this condition is obscure. Among the many that have been suggested are: cold, injuries to nerves, anemia, malaria, and the medicinal use of arsenic. *Symptoms.*—The affection begins with neuralgic pains, either of a burning or lightning-like character, with slight febrile phenomena, followed by the appearance of papulovesicles along the tract of pain; these soon become vesicles situated on bright red, highly inflamed bases. The vesicles are about the size of pin heads, or, perhaps, a little larger; usually discrete, although they frequently coalesce, forming irregular patches, appearing in groups until the third to the fifth or even tenth day, when they gradually desiccate, and at the end of the second week nothing remains except occasionally a slight scar, which may disappear or become permanent. When the eruption is at its height, it is perfect in its anatomic formation, each vesicle being well shaped and seated on a bright red, inflamed patch of skin, and distended with a translucent, yellowish fluid. The vesicles show no tendency to rupture spontaneously. In rare instances they may become purulent, hemorrhagic, or gangrenous. The eruption is almost invariably confined to one side of the body, although in rare instances it is seen upon both sides. It is usually found upon well known nerve tracts. Recurrence is rare. *Treatment.*—The pain will require the administration of antipyrin, gr. xv, every three or four hours; phenacetin, gr. v, every three hours; sodium salicylate, gr. x to xv, every three hours; or if very severe, morphine, gr. ⅛, and atropine, gr. 1/100, hypodermically near the lesion. A combination of zinc phosphide and nux vomica is sometimes of value. Locally, aristol, boric acid, zinc oxide, and similar powders dusted over the lesions are of value. Flexible collodion, containing morphine, painted over the vesicles serves to protect them and lessen the pain."—(Hughes' *Practice of Medicine.*)

10. ERGOT. *Therapeutic indications:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headache, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

OBSTETRICS AND GYNECOLOGY.

1. The blood-pressure should be taken during pregnancy, because a continuously increased pressure is one of the earliest evidences of a toxemic condition.

2. The patient should be advised to avoid indigestible or very highly seasoned articles of food; her diet should be nutritious and sufficient. In patients who have previously had unduly heavy children it would be well to restrict the carbohydrates and fluids during the last two or three months of pregnancy. The tendency to constipation, which may be increased during pregnancy, should be overcome by laxative foods or fruit.

3. Multiple pregnancy may be diagnosed by the following signs: (1) The abdomen may be irregular in shape and may show a sulcus indicating the space between the two fetal sacs; (2) persistent and increased tension of the uterine walls; (3) two fetal heart sounds

may be heard; (4) multiplicity of small parts; (5) two fetal heads or backs may be palpated; (6) diminished fetal mobility. Sometimes it is difficult to diagnose the condition before the birth of one child.

4. At times it is difficult to make a differential diagnosis between uterine fibroma and pregnancy; but *if you can afford to wait the course of time will prove the* diagnosis. The following table is from Dudley's *Gynecology:*

PREGNANCY.	FIBROIDS.
1. History of pregnancy.	1. Absent.
2. Uterus soft and elastic.	2. Usually irregular in form and harder.
3. Consistence varies with uterine contraction.	3. Uterine contractions not marked—very important sign.
4. Cervix soft.	4. Hard or not so soft.
5. Regular and uniform increase in size of uterus.	5. Growth slower and irregular.
6. Later, ballottement, fetal heart-tones.	6. Absent.
7. Palpation of fetus.	7. Palpation of myoma.

5. When a hand is found presenting: In head presentations if the condition be diagnosed before rupture of the membrane nothing should be done until the cervix is completely dilated. Then the hand may be pushed up to allow the head alone to engage in the brim. If this fail, forceps may be applied to the head if there be no risk of catching the arm, or version may be carried out. In extracting with forceps the arm may slip up. When the case is made out only after the arm is well engaged in the brim, the head should be delivered with forceps. In breech presentations, sometimes the hand presents. Nothing need be done. The hand may or may not slip up.—(Jewett's *Obstetrics.*)

6. Symptoms of death of fetus are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time crepitus of its cranial bones may be elicited.

Fetal death. Causes: Syphilis, apoplexy of placenta or membranes, diseases of ovum or uterus, nephritis, poisoning (including tobacco and alcohol). *Positive sign:* Failure, after repeated examinations, to get the fetal heart sounds and movements after they have been obtained on previous occasions. *Treatment:* Induction of abortion or premature labor, at once, with complete removal of the contents of the uterus.

Questions will be on the line of the *cause* of the condition; and advice will be given about the treatment of the causal condition.

7. *Pus tube*, or pyosalpinx, or purulent salpingitis is a "disease caused by the septic and gonorrheal varieties of endometritis. The inflammation of the uterine mucosa extends directly to the tubes and produces in them the same form of infection. Purulent salpingitis is a very common disease, and is, with very few exceptions, the cause of the various inflammatory lesions met in the pelvis. The vast majority of cases that are due to sepsis are puerperal in origin, and they even exceed in number those that are due to gonorrhea. In nearly all instances where the endometrium is the seat of a gonorrheal or septic infection the tubes become involved; on the other hand, however, we undoubtedly meet cases in which the disease remains confined to the uterine cavity and the oviducts escape entirely.

"There are several ways by which the infection may escape from the tube to the adjacent structures: 1. The purulent secretion may escape through the abdominal opening of the tube. 2. The infection may be carried by the lymphatic channels through the walls of the tube. 3. The pathogenic organisms may penetrate the mesosalpinx and infect the cellular tissue of the broad ligament. 4. A pyosalpinx may rupture and its contents escape into the pelvic cavity. 5. Adhesions may form between the tube and the surrounding structures and later on the infection may pass through them to the adherent organ.

"A gonococcus infection starts as a subacute or a chronic condition and is not, as a rule, immediately dangerous to life. A streptococcus infection, on the other hand, is acute or active from the beginning and is always perilous to life from the first. Both forms usually cause permanent damage to the tubes as well as pelvic adhesions, sterility, and chronic invalidism, and they also endanger the life of the patient from recurrent attacks of peritonitis, fresh infection, rupture of a tubal abscess, and exhaustion following a prolonged suppuration."—(Ashton's *Gynecology.*)

8. OPHTHALMIA NEONATORUM. *Prophylaxis:* Whenever there is a possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver immediately after birth.

Treatment: Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

9. *Icterus neonatorum* is caused by the resorption of bile, due to the small caliber of the biliary duct; or to bacterial infection of the blood. Treatment is, as a rule, unnecessary; a mild laxative or enema may be given; in severe cases treatment is of no use.

10. *Caput succedaneum* requires no treatment as it disappears gradually within a few weeks.

SURGERY.

1. The source of the blood should be determined. "In *renal* hematuria the blood is intimately mixed with the urine, individual red cells are usually decolorized, and blood casts are found. If the blood is from the *pelvis of the kidney*, or the *ureter*, coagula corresponding in shape to the pelvis, or the ureter, may be found. It may be necessary to employ ureteral catheterization. In hemorrhage from the *bladder*, the blood and the urine are not so distinctly blended, the clots may be of such an irregular form and large size as to indicate their origin, and the individual cells retain their normal appearance. The cystoscope may be required to determine this point. If the blood is from the *urethra* it ordinarily drips away spontaneously, and if the urine is voided the last portion is clear."—(Butler's *Diagnostics of Internal Medicine.*)

2. With no more information than that given in the question I would not advise anything to be done.

3. *Splenectomy is indicated* in some cases of movable spleen, hypertrophy, injury and tumors of the spleen.

4. *Osteomyelitis of the tibia.* "Treatment must be very prompt. A free incision must be made through the periosteum and the pus evacuated. In any case, whether pus is found or not, the surface of bone must be gouged away to expose the medulla freely, and any gangrenous tissue scraped out. The cavity must then be washed out and freely drained. The wound in the soft structures is not closed in any part. If symptoms of pyemia occur, it may be necessary to amputate the limb through the joint or bone above, so as to cut off the source of the emboli. When a large portion of, or the whole diaphysis is necrosed there are two courses; either to cut short the disease by removing the dead portion at once, or to leave the sequestrum to stimulate the formation of an involucrum. Where there is a single bone, as in the arm and thigh, the sequestrum is left; where there is a double set of bones, as in the forearm and leg, the sequestrum is removed at once. Celluloid, zinc, and ivory rods have been inserted to stimulate osteogenesis. In most cases it is doubtful how much bone is actually dead, so that it is better to provide free drainage, wait six weeks or longer, and then open up the cloacæ in the newly formed involucrum to remove the sequestrum. The cavity heals by granulation."—(*Aids to Surgery.*)

5. *Artificial pneumothorax* is a condition of pneumothorax produced by the injection of nitrogen (or other gas) into the pleural sac; it has been used for the cure of phthisis.

6. "*Pulmonary abscess* when acute is usually a sequel of septic pneumonia, and is often associated with gangrene of the lung. Chronic abscess may be due to the spread of an empyema or of a hepatic abscess to the lung. The sputum is abundant, yellow, and cream like, and contains elastic fibers and hematoidin crystals. The physical signs of a cavity in the lung are present, and this may be localized by the *x*-rays. The result of pneumonotomy in such cases is on the whole satisfactory. Pyemic abscesses are usually multiple, and therefore not so amenable to surgical treatment."—(Thomson and Miles' *Manual of Surgery.*)

7. "*Fat necrosis* is a common concomitant of acute hemorrhagic and gangrenous pancreatitis, and may be observed also in association with chronic suppurative and chronic interstitial pancreatitis. It occurs as disseminated or multiple minute foci in or upon the pancreas, and as larger foci (2 to 3 mm. in diameter) in the fat of the omentum, and of the subperitoneal and retroperitoneal tissues, and sometimes in the pericardial and subcutaneous fat. Extremely large foci have occasionally been observed. The foci are whitish or yellowish and opaque (in marked contrast to the translucent yellow of the normal fat), and they are frequently surrounded by a narrow zone of hemorrhage. They consist of lime and certain fatty acids. Flexner has demonstrated the presence of the fat splitting ferment (presumably that of the pancreatic juice) in distant necrotic foci (subcutaneous and peritoneal fat), as well as in the foci in the immediate vicinity of the pancreas. Fat necrosis is believed to result from diffusion of the pancreatic ferment in consequence of hemorrhagic destruction of the gland or obstruction of the ducts."—(Kelly's *Praetice of Medicine.*)

Treatment: "As the diagnosis of these conditions can rarely be made with certainty, an exploratory laparotomy must be performed. After the abdomen is opened, the recognition of fat necrosis, evidenced by the minute, opaque, white areas scattered through the omentum and mesentery, and the presence of a serohemorrhagic effusion, go far to establish the diagnosis. The most simple and direct access to the pancreas is obtained by making an opening in the gastrocolic omentum, pulling the stomach upwards and the transverse colon downwards, and incising the posterior parietal peritoneum. The gland thus exposed is then palpated so as to localize the area of disease, and, after packing off the peritoneal cavity, the pancreas is incised. Necrosed tissue is removed with the spoon or scoop, and the cavity packed with gauze. If there is an accumulation of blood, as in the hemorrhagic form, this is removed, and, to prevent further extravasation, the cavity must be firmly packed. If there is a collection of pus, provision must be made for drainage either through the abdominal wound or through a separate opening made behind in the right or left costovertebral angle. If there is also cholelithiasis, this must be dealt with later."—(Thomson and Miles' *Surgery.*)

8. *Etiology of cholelithiasis.*—Any obstruction to the free outflow of bile, catarrhal inflammation of the bile ducts, bacteria, foreign bodies; excess of carbohydrate diet and sedentary habits, with constipation are predisposing causes.

9. *Anastomosis of blood vessels* has been employed in cases of threatened or commencing gangrene of the extremities, associated with arteriosclerosis.

10. If practicable, the whole mass should be removed; if there are extensive adhesions removal is impossible. Secondary growths, and metastasis to viscera are likely to occur, and exhaustion, shock, and death ensue.

PEDIATRICS AND TOXICOLOGY.

1. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° Fahr., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60° Fahr."

2. CHOLERA INFANTUM. *Causes:* It is caused by microorganisms. It is very rarely seen in breast-fed babies, being met with almost invariably in those artificially fed. It is most common among the poor of large cities during very dry and hot summers, and it often assumes an epidemic form. *Treatment.*—When vomiting is very severe, the stomach should be washed out with a warm solution, such as saline, or ½ to 1 per cent. boric acid, or 1 per cent. sodium bicarbonate, or a solution of resorcin, 1 in 5,000. After this drop doses of the glycerin of carbolic acid in a teaspoonful of water every hour should be tried, or small doses of calomel placed on the tongue may be given. All food by the mouth had better be withheld, and only small pieces of ice given to suck, or if the child be very young, the ice may be wrapped in a cloth, which it may be allowed to suck. At the same time a sinapism is applied to the epigastrium, one part of mustard to four parts of flour. Dr. Holt relies most on the hypodermic injection of morphine and atropine, and he advises repeated small doses as being preferable to one large dose. For a child a year old 1/50 grain of morphine with 1/800 grain of atropine may be injected and repeated in an hour. It soothes, and the child falls into a quiet sleep for a few hours, after which the stomach will retain small quantities of light nourishment. After this lull in the attack, one or other of the antiseptic drugs may have a trial."—*Aids to Diseases of Children.*)

3. *Indications of pyloric stenosis.*—Persistent and projectile vomiting, scanty feces and urine, emaciation, dilated stomach with collapsed intestines; sometimes a thickening around the pylorus may be felt.

4. *The treatment of chorea* consists in rest and the avoidance of overexertion of any kind. Correct any error of refraction or gastrointestinal disturbance. Tea, coffee, candy, cakes, and sweets should not be a part of the diet of children. Milk should be given in large quantities. A daily warm bath, systematic massage, and electricity to the spine are useful. Chloral and bromide are occasionally necessary to control the movements. Arsenic in Fowler's solution, three drops three times daily, diluted, may be given to a child 6 to 9 years of age, increasing one drop every day. Constitutional symptoms of the arsenic-poisoning should be watched for carefully. When anemia is present, iron in Blaud's pill, gr. 5-15, or the tincture, gtt. 10-30, three times daily, may be given to a child. Quinine may be given in large doses. The fluid extract of cimicifuga (♏ 10-20) may be given to a child 6 years old, increasing the dose until headache, dizziness, etc., are produced. Trional and chloralamid are indicated if the sleep is disturbed. Recurrence is prevented by the continuance of the treatment just given. Complications, such as rheumatism and endocarditis, will require the same treatment as if occurring independently. The building up of the general health and moral and suggestive treatment are useful in all forms of the disease.—(*Pocket Cyclopedia.*)

5. *Dangers incident to removal of tonsils and adenoids:* Laceration of surrounding tissues, hemorrhage, asphyxia, death from the anesthetic particularly in children who show evidences of the status lymphaticus.

6. *Varieties of congenital hernia: Congenital inguinal hernia*, in which the sac is formed by the funicular process; sometimes the sac lies above and distinct from the tunica vaginalis (*funicular* variety); and sometimes the sac is continuous with the tunica vaginalis (*vaginal* variety). *Treatment* consists of a well fitting truss; after three years of age operation may be considered. There is also a *congenital umbilical* hernia, in which the intestine protrudes into the base of the umbilical cord; it is a rare condition and demands prompt laparatomy with reduction of the intestine, and closure of the umbilical opening by sutures.

7. "*Acute hydrocephalus*, is a synonym for tuberculous meningitis. *Chronic hydrocephalus*, to which the term is now usually restricted, may be (1) *Congenital.* The causes are not known, but there is sometimes a family proclivity to the affection. (2) *Mechanical:* due to obstruction of the veins of Galen, as by the pressure of a tumor, or to blocking of the foramen of Mengendie, as by meningitis, or of the iter. (3) *Idiopathie.* This form is due to serous effusion into the ventricles, and may occur at any age. A serous meningitis and an angioneurotic condition have both been invoked to explain it.

"*Treatment* is very unsatisfactory, if not hopeless. (1) Pressure by strips of plaster or elastic bands. (2)

Puncturing at various intervals, and drawing off the fluid. The ventricles may be tapped, and direct drainage established, or the fluid may be more slowly removed by puncture of the subarachnoid sac in the lumbar region."—(Wheeler and Jack's *Handbook of Medicine.*)

8. *Symptoms of toadstool poisoning:* These sometimes do not appear for several hours, and there may be no disagreeable taste to indicate the poisonous nature of the food. Then there is likely to be sudden and great prostration, with cold perspiration, headache, amaurosis and stupor, or wild delirium. There is frequently marked cyanosis, and sometimes icterus. Usually there is some fever, with rapid, feeble pulse. The urine is scanty and albuminous or bloody and sometimes suppressed. Death usually occurs in from eighteen hours to three or four days from exhaustion or cardiac paralysis. There is usually much abdominal pain and sometimes diarrhea, with rice water discharges closely resembling cholera. *Treatment:* Elimination of the poison by emetics and cathartics and the hypodermic use of atropine. The stomach tube is not usually very successful in removing the poisonous material, as it clings tenaciously to the walls of the stomach. There is no chemical antidote known. Atropine is the best physiologic antidote and frequently gives very prompt relief.—(Riley's *Toxicology.*)

9. *Symptoms of belladonna poisoning:* In the first stage, that of delirium, there are, dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration.—(Witthaus.)

The *symptoms of poisoning by strychnine* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

10. *Chronic lead poisoning:* "The early symptoms are often very obscure. Various symptoms of indigestion are first noticed with progressive emaciation and mental depression, with anemia and a peculiar whiteness of the skin probably due to contraction of the peripheral capillaries. Sometimes a blanching of the fundus of the eye or amaurosis due to a similar contraction of the capillaries is an early symptom. Then a twisting grinding pain around the umbilicus comes on and gradually becomes more severe. It may be relieved by pressure. The abdomen is hard and retricted. As a rule the bowels are obstinately constipated, but occasionally there may be scanty, hard, clay colored, painful evacuations. The urine is diminished or suppressed, the skin sallow, cold, and clammy, the breath fetid, mouth and throat dry, and a blue line on the edge of the gums next the teeth, most noticeable next to the incisors, which are discolored and brown. This blue line may be developed as early as three days after ingestion of the poison. The gums are tender and bleed easily. The pulse is generally decreased in frequency. As the case progresses, or after repeated attacks, paralysis begins to appear, affecting chiefly the extensor muscles of the forearm, though not limited to them, sometimes extending to the interossei, and generally affecting first those muscles which are most imperfectly supplied with blood. The paralysis is symmetrical, generally affecting the corresponding muscles in both arms, and is often preceded by numbness of the fingers and hands. The affected muscles become more or less atrophied, leading to general debility ("lead palsy"). The nervous system becomes affected, and headache, vertigo, amblyopia, amaurosis, delirium (sometimes furious) and epileptoid convulsions precede death. Albuminuria is frequently, and jaundice occasionally, present. In many cases severe pain in the joints is one of the most prominent symptoms, probably due in some manner to interference with the functions of the kidneys.

Treatment: "For the removal of lead from the tissues with which it has entered into a more or less stable combination potassium (or sodium) iodide in doses of 10 grains three times a day has long been recognized as one of the best. It is but just to say that its efficacy has recently been called in question by some of our best clinicians. Warm sulphur baths have been found useful. Atropine or morphine and atropine may be given hypodermically for relief of the colic. Cocaine hypodermically has also been successfully used to relieve both the pain and constipation. Calomel and gamboge, castor oil, or olive oil, may be given to overcome the constipation. Belladonna or hyoscyamus may be added with advantage to either of the cathartics. Alum sometimes acts well as a cathartic in these cases. As a prophylactic measure tea as a drink and a dose of sulphur occasionally, both act by precipitating lead from solution."—(Riley's *Toxicology.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 11
Arizona*	J. W. Thomas, Phoenix	Phoenix	Jan. 4
Arkansas	T. J. Stout, Brinkley	Little Rock	Nov. 9
California	C. B. Pinkham, Sacramento	Los Angeles	Dec. 14
Colorado	David A. Strickler, Empire Building, Denver	Denver	Jan. 4
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 14
Dist. of Col'ba.	E. P. Copeland, Washington	Washington	Jan. 11
Florida*	E. W. Warren, Palatka	Jacksonville	Dec. 7
Georgia	C. T. Nolan, Marietta	Atlanta / Augusta	Jan 1
Idaho*	Charles A. Dettman, Burke	Wallace	
Illinois	C. S. Drake, Springfield	Chicago	Jan.
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 11
Iowa	G. H. Sumner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Feb. 8
Kentucky	J. N. McCormack, Bowling Green	Louisville	Dec. 14
Louisiana	E. L. Leckert, New Orleans	New Orleans	Dec. 2
Maine	F. W. Searle, Portland	Portland	Nov. 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 14
Massachusetts*	W. P. Bowers, State House, Boston	Boston	Nov. 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann. Arbor	June, 13
Minnesota	T. McDavitt, St. Paul	Minneapolis	Jan. 4
Mississippi	E. H. Galloway, Jackson	Jackson	
Missouri	J. A. B. Adcock, Jefferson City	St. Louis	Dec. 13
Montana*	Wm. C. Riddell, Helena	Helena	April 4
Nebraska	H. B. Cummins, Seward	Lincoln	Nov. 10
Nevada	S. L. Lee, Carson City	Carson City

†Applicants should in every case write to the secretary or all the details regarding the examination in any particular State

Tubercle Bacilli in the Circulating Blood.—C. R. Austrian and L. Hamman were unable to demonstrate the presence of tubercle bacilli in the blood in a single instance notwithstanding the fact that many of the patients when examined were in the last stages of the disease. In animals, when the disease remains localized in the lungs, tubercle bacilli are not found in the circulating blood. When the disease becomes generalized, as it does in the late stages of pulmonary infection and very soon after overwhelming intravenous injections, circulating tubercle bacilli are frequently demonstrable. The evidence presented points strongly against the mobilization of tubercle bacilli by the injection of tuberculin. A larger number of positive results was revealed by the method of animal inoculation than by the microscopical examination of the sediment obtained by treating blood according to the acetic-acid-antiformin method.—*Bulletin of the Johns Hopkins Hospital.*

RHEUMATISM AND THE SKIN.

BY WILLIAM P. CUNNINGHAM, A.M., M.D.,

NEW YORK.

IN our feverish quest of the nimble bacillus we are apt to lose sight of the fact that fire will burn and cold will freeze and trauma produce inflammatory reaction. Tracing etiology through the microscopic lens we are deflected from the consideration of the truths discernible to the naked eye. We discredit the evidences of our senses and the deductions of our reason in referring all pathological manifestations to the activity of microorganisms. A blow on the head will kill without the intervention of a miliary aneurysm caused by the *Spirochæta pallida*. A wound of the chest will kill without the intervention of the pneumococcus. Fright will paralyze the cardiac ganglia without the preparatory meddling of the *Bacillus rheumaticus*. Carbolic acid will rapidly destroy the blood stream not only without the cooperation of any description of bacillus but with the actual coincidental destruction of every such wanderer as it may encounter in its onward sweep. Diabetic gangrene will inexorably advance upon the vital defences with never a suspicion of preliminary microbic complicity, the entire process being chemical and mechanical. The sudden exposure of an overheated head to the gratifying influence of a current of air may invite the terrifying phenomenon of Bell's palsy. The sudden checking of the general perspiration may eventuate in a prompt suppression of urine and all the other manifestations of acute nephritis. Prolonged defiance of the summer sun may bring about the extremely dangerous cerebral congestion denominated insolation. Prolonged subjection to the winter's cold may result in the loss of fingers, toes, and ears and the production of peripheral neuritis. The inordinate ingestion of alcohol will arouse a frenzy equal in all its horrifying details to that of the best authenticated microbic delirium. It will shrink and harden the liver and make the rectum bloom with hemorrhoidal profusion. It will bring to the nose and cheeks a brilliant efflorescence, occasionally diversified with shades of regal purple. Persistence will effect a change in the contour of the organ characterized by the development of irregular lobulations scientifically described as rhinophyma and popularly derided as "tomato" nose. And all this mischief comes about with never a hint of a microorganism! The mechanical causation of intestinal stasis with its far-reaching evil consequences, has been determined by the abdominal operators, and the question of germs becomes important only after the field has been long prepared by defective drainage. The various bacilli that haunt this serpentine sewer, are regularly swept away by the brisk efficiency of unimpeded peristalsis, and have no time to generate and exploit their peculiar toxins. In bowels that are regularly and effectually evacuated no opportunity is afforded for the multiplication of infective bacteria. Intussusception will plunge a rugged active child into an agonizing fight for life, with the implication of bacteria a secondary consideration. An endarteritis will cut off the circulation at a minute point in the gastric mucosa and the acid gastric juice will eat into the undefended tissue, producing a gastric ulcer without the assistance of any microorganism. Exophthalmic goiter, a common clinical picture of the most distressing character, is never referred to a microbic origin. The ingestion of certain vegetable substances induces a train of symptoms varying with the identity of the toxic alkaloids. We recognize the injurious effects of aconite, morphine, conium, tobacco, *et al.*, and realize that here we have definite and well differentiated pathological conditions in which there are no germs involved whatever!

The foregoing illustrations taken at random from hundreds that might be cited are not intended to discredit the incalculable service of the microscopist in the study of pathology. It would be idle and absurd to make any such attempt. The triumphs of his genius and patience are too striking and too numerous to suffer any diminution at the hands of ignorant detraction. The typhoid bacillus, the pneumococcus, the Klebs-Loeffler bacillus, the streptococcus, the staphylococcus, all the mighty host of pathogenic pigmies that swarm the defences of our anatomy seeking a point to break down our resistance, testify eloquently to the mental prowess and indefatigable energy of the man with the lens. But lest, in our intense enthusiasm, we be carried away from a correct perspective of the origin of disease, it is essential to give the germ only that consideration to which it is actually entitled and devote to other influences equally pernicious, a reasonable share of assiduity! For instance what a lamentable loss to medical science would be a blotting out of the discoveries of biological chemistry! Had the great minds that have evolved the fascinating principles of colloid chemisty been diverted from their purpose in the quest of microorganisms how gravely would the health of man have suffered!

With colloid chemistry came the great truth of acid intoxication. With this came the clearing up of many obscure phenomena, and the hopeful management of disease on the rational basis of neutralization. It might be impossible to prevent the assault of the germ upon the susceptible tissues, it might be quite as impossible to destroy it after its assault had been effected, but it was established that one of the gravest consequences was the production of an acidosis, and this could be met and counteracted by the administration of alkalies and neutral salts. The preservation of a normal meta-

bolism, and adequate elimination depend upon the absorptive capacity of the colloidal tissues of which our parenchyma is composed. If this is at its normal level function will be smooth and effective. If it is increased there occurs a turgescence of the thirsty tissues mechanically blocking the process of secretion, and wholly or partially putting the organ out of action. The cells of the kidney swell and we have suppression of urine. The cells of the cerebrum swell and we have stupor, delirium, and coma —all the manifestations of the old-fashioned but correctly and scientifically denominated "wet brain!" The cells of the lungs swell and we have a pulmonary edema. The colloid tissues of the eye swell and we have the increased ocular tension known as glaucoma. The colloid tissues of the larynx swell and we have edema glottidis. In general as well as local edema we have this same increased capacity of the tissues to absorb water. And invariably the agency thus effecting the hydration of the colloids is acid intoxication. Acid intoxication might be defined as the presence of acid in the tissues in sufficient amount to increase their absorptive powers. The smallest conceivable amount of acid will do this to a certain degree if it is not promptly neutralized! We are apt to picture acid intoxication as a "delirious" condition due to the circulation of a large amount of acid through the system. The actual fact is that it means the presence in the blood or cells of any (even the minutest) quantity of unneutralized acid toxin. Acid toxemia would be a more illuminating terms. A true acidemia means rapid dissolution. This is encountered only in circumstances such as carbolic acid poisoning. By acidemia we ordinarily intend to convey the impression of a lessened alkalinity or the tendency to the development of acid in excess of the system's power of immediate neutralization. It is to this tendency that the term "acidosis" is applied and while not an exactly scientific term it is so convenient and so generally accepted that its rejection would be a positive disadvantage.

Every pathological condition interfering with the proper oxygenation of the cells of the economy induces an acidosis. This is plain to see. If the cells do not receive their adequate supply of oxygen, the waste product (carbonic acid), accumulates and there is an acid intoxication local or general according to the extent of the asphyxia. If it is universal as in the acute attacks of cardiac asthenia, the cyanosis of the skin and mucous membranes, is accompanied by the agonizing struggle of pulmonary edema and the bulging eyes and ringing ears of edema of the brain. In general anasarca, we observe the consequences of the same cause more gradually developed. The extremities feeling first the loss of oxygen, because of their remoteness from the inefficient heart, in response to the local preponderance of carbonic acid absorb water from the blood and swell into the shapeless cold and purple masses that we frequently encounter. As the heart steadily flags in its efforts to overcome its handicap the edema advances up the limbs and eventually invades the abdomen and thorax. If by the aid of digitalis and recumbency the relative propulsive force of the left ventricle is sufficiently increased, oxygen begins to find its way again into the acidulated tissues and they at once begin to yield up the water they had absorbed. The kidneys suffering like the subcutaneous tissues for want of oxygen are engorged and unable to perform their function and oliguria results. This may proceed also from advanced arteriosclerosis where we have practically the same defect of oxygenation owing to the insuperable resistance to the action of an otherwise capable heart. It is a noteworthy fact that anesthetics such as alcohol, chloroform, and ether, and poisons such as morphine, atropine, cocaine, and strychnine, and the toxins of the pneumococcus, *Bacillus typhosus*, et alia sui generis, and metallic salts such as arsenic and lead, because of their tendency to reduce the amount of oxygen in the organism at large have the same effect upon the kidney as inadequate circulation, and induce partial or complete suppression.

An abnormal dietary throwing upon the eliminative organs too much of the product of protein metabolism overturns the nicely balanced neutrality of the colloids, and promptly absorbing water from the blood and lymph channels they swell to proportions more or less obstructive to function and we get a picture of scanty urine, "bilious" vomiting, and "congestive" headache.

The summary of the teaching of colloid chemistry is that any ingesta, increasing the acidity or upsetting the neutrality of the cell, or any physical condition lessening the supply of oxygen to the same will cause it to become waterlogged and incapable of efficient action. The consequent symptoms vary with the peculiar function with which it is endowed. If the grand basic principle is kept in mind, the details of its application will afford very little difficulty. If you recall that your pneumonia patient is afflicted not only with a congestion of the lung, but also with an acidosis consequent on insufficient oxygenation of the blood, you will have a clearer grasp of the problem to be met and will resort to measures much more beneficial to the sufferer, than if you hammer away at the one fixed idea of whipping up his heart to overcome obstruction. It is obvious that oxygen being the serious lack, it should be provided if possible from the beginning and not be deferred until cyanosis proclaims the desperate state of the asphyxiated tissues. Better to prevent this deplorable contingency than engage in a mortal combat upon its appearance. Having endeavored to bring out the essential points in the problem of acidosis it will be interesting and instructive for us to note their applicability to the question of dermatology.

The etiology of rheumatism is disputed. On the one hand it is asserted to be an infective disease with a long suspected but as yet unidentified bacillus. With equal positiveness it is asserted to be a manifestation of disordered metabolism due to improper nutriment in persons predisposed. Still other partisans lay it to the door of intestinal stasis and affect an airy indifference to both the microbic and metabolic hypotheses, maintaining with a fair show of reason that if it were not for the inactivity of the gut the germ would never effect an entrance into the circulation or the metabolism would never be sufficiently disturbed to constitute a toxemia. Leaving this controversy to those with the time and inclination to pursue it let us be content with the practical conclusion that under any theory of origination, the eventual process is an acidosis of the intensest type, and must be dealt with accordingly. The urine is extremely acid, the perspiration also, and the normally alkaline saliva now turns litmus red. There are a few cutaneous abnormalities associated with rheumatism so persistently that there has grown up a consensus of opinion regarding them. Purpura is one of these. It is common enough to come within the experience of every clinician. It is so readily recognized that it is

rarely overlooked. It occurs on the lower extremities and its appearance may be punctate, guttate, nummular, or fantastically traced in large irregular patches in the skin. The spots are usually not uniform and the outlines, while corresponding in a general way to the terms employed, are ragged and uneven. There is a preceding or concomitant arthritis as a rule.

Erythema multiforme, as its name suggests, is an eruption of a varied configuration, appearing suddenly and accompanied by a sensation of heat. There may be erythematous patches, large flat papules, vesicles, or bullæ. There are sometimes wheels within wheels, that is circinate lesions surrounded by others. Three rings may be thus disposed. Erythema iris is the title given to this peculiar and attractive arrangement. The inner circle being the oldest begins to fade the first and assumes the hue of a receding ecchymosis. If there are three rings there will be three shades of color. This variegation has been held to bear a slight resemblance to the iridescence of the rainbow. Hence the picturesque nomenclature. If the eruption is vesicular it may follow the same disposition, and we shall have a central vesicle surrounded by a rim of vesicles or even by two. This has been dubbed herpes iris. The ordinary flat papules that constitute the greater part of the eruption are frequently marked with a characteristic central depression. They have been compared to miniature targets.

Occasionally bullous lesions testify to the severity of the exciting cause. These may be of any size and many forms. They may be round, oval, crescentic, angular, or stellate. A single bulla may occupy an entire ear. A string of bullæ may encompass the neck like a rope of pearls. They may be few or numerous. They may occur alone or interspersed with the commoner manifestations of the disease, whose favorite sites are the wrists and ankles, the back of the hands and fingers. The sides of the neck may be invaded, and in the furious bullous outbreaks the face and ears also. This dermatosis is a consequence of rheumatism. This view is sustained by the associated arthritic pains, that are generally demonstrable; by the discovery of the lesions of erythema multiforme as integral parts of Schönlein's disease (an admittedly rheumatic affection); by the speedy disappearance of the process under active antirheumatic medication. Schönlein's disease might be described as a mélange of purpura, erythema multiforme, urticaria, and angioneurotic edema, appearing in the vicinity of a swollen painful joint. A case of this sort will display all the characteristics of all the dermatoses of its composite identity. There will be splotches of purpura, flares of erythema, the uprearing of bullæ, and the rapid alternation of itching wheals and angioneurotic turgescence. Some of the bullæ will be hemorrhagic, proving the common origin of both processes.

Conceding the rheumatic etiology of erythema multiforme we are logically compelled to do the same for urticaria, and angioneurotic edema. They are so closely related that frequently we must hesitate in deciding which is urticaria and which its own first cousin. With urticaria goes angioneurotic edema, for there can be no question that one is the Lilliputian and the other the Brobdignagian representative of the same family. The responsibility of rheumatism in this relation is furthermore confirmed by the structure of the lesions. The flat papule of erythema multiforme and the wheal of urticaria and the colossal tumefaction of angioneurotic edema, are all due to the rapid absorption of water by the colloid tissues of the skin under the stimulus of an acid irritation. The competency of an acid irritation to effect such a result is acknowledged in the case of bee-sting and of contact with poison ivy. The joints in rheumatism react in precisely the same way as the cutaneous fabric. The colloids absorb water and swell, producing the gross evidences of inflammation. Into the cavity of the joint in accordance with the tendency of swollen colloids to exude a dilute liquid protein colloid, filters a serous fluid hitherto styled a transudation. Into the other serous cavities a like exudation occurs and we are confronted by a pleurisy with effusion, a pericarditis with effusion, or a hydroperitoneum. This separation of a dilute solution of itself from the swollen colloid is known as "syneresis." In the superficial edemata the presence of free fluid in the loose areolar tissues is explained in the same way. Syneresis may be fixed in the mind by translation into the colloquial expression "running away with oneself." Its primary meaning is coalescence and its secondary meaning is "carrying away with one." First the water combines with the colloid and then both water and colloid flow off together. When the kidney swells in nephritis the appearance of albumin in the urine is an illustration of syneresis. A certain amount of liquid protein is given off, the acidity that causes the turgescence also effecting a solution of the colloid.

The explanation of purpura on the colloid hypothesis at first glance affords considerable difficulty. Here we have a question of the escape of blood corpuscles from the capillaries. The theory of diapedesis, with its dual supposition of stomata in the blood vessels and an increased arterial pressure driving the corpuscles through these convenient apertures has been effectually exploded. In its place we are offered the proposition that the capillaries swelling under the influence of an acid contact the denser corpuscles are able to drive through the walls of diminished resistance. This has been shown by experiments *in vitro* to be a rational explanation.

Erythema nodosum with its pinkish painful protuberances on the crest of the tibia is of rheumatic origin in the opinion of most observers. The therapeutic test is speedily confirmatory. Confusion is little likely to occur if the clean-cut characters of the outbreak are kept in view. The sudden appearance concomitantly or in rapid succession of perhaps a dozen nodules along the anterior aspect of the leg, decidedly painful on motion and pressure, bright red in color, and ranging in size from that of a hazelnut to that of a walnut, is paralleled by no other cutaneous malady. Careless examination might confound them with the lesions of erythema induratum, which are of tuberculous origin, are confined to the back of the leg, and differ decidedly from the others in being sluggish, painless, and purplish.

If the nodules of erythema nodosum should happen to become bunched on the shin the resulting aggravation of the pain and coalescence of the areas of redness might suggest the diagnosis of cellulitis: erysipelatous or otherwise. Deliberation in searching for distinguishing signs and illuminating history is certain to be rewarded.

The nodosities that are so frequently observed upon the distal extremities of the phalanges and are liable to develop anywhere in the course of the

tendons or in the fibrous tissue, are unequivocal evidence of the rheumatic diathesis. This word "diathesis" by the way is falling into disrepute under the icy contempt of the up-to-the-minute pathologist. Being a survival of the nomenclature of the discredited humeral causation of disease it can find no place in the glossary of bacteriology. It means a state or disposition. We wise men of this generation know that there is no diseased "state" or "disposition." Disease is the result of the activity of microorganisms. It is a reaction. It would be as rational to talk of a burning building being in a "state of fire" as to talk of the human organism being in a state of disease! Disease is action—reaction, if you like. That implies movement, not stasis. This argument is all very well and all very true, but there are considerations that qualify its sweeping applicability, and mitigate the offense of the pathological heretics to whom it is so cuttingly applied.

Language is the instrument of thought, not its master. We speak of mental states. We even say that the mind may be in a state of perturbation! If there could be any more contradictory declaration than that it would be difficult to frame it. A state —a standing still of excessive excitement! We even transcend this absurdity, however, and assert quite casually that a person is in a delirious state! According to our dicriminating philology he may also be in a "feverish" state, or a sweating state, or a critical state, or in any other state implying the negation of state—except the rheumatic state or diathesis. Note the folly of allowing the language to dictate the thought instead of serving as its humble and malleable instrument! The word diathesis is not to thus be cavalierly dealt with. Properly understood it has as much right to existence as many other accepted words that will not stand acute analysis. Let us speak of the rheumatic diathesis as indicating the subacute manifestations of that disease or susceptibility to the active agent whatever that may be. The fibrous nodes from which we have become separated by our incursion into the field of etymology are noted then in those of the rheumatic diathesis. They are supposed to be the analogue of the growths upon the cardiac valves that narrow the orifice in some instances and in others prevent the proper closing of the leaflets. These nodes may be painless or, owing to the pressure exerted on the nerve filaments, may be very painful. They are a nuisance and an impediment to the free employment of the fingers. The fibrositis of the heels with which we are unfortunately too familiar in our experience of rheumatic subjects is in the same pathological classification. While not strictly a dermatological matter it often comes to us for elucidation under the impression that there is something amiss with the skin. It is rebellious to treatment, and distressing to the last degree.

The finger nails frequently show the alternate flash and recoil of the blood in the capillaries owing to their abrupt distention and collapse in aortic regurgitation. The hypertrophied left ventricle sweeps the blood onward with a powerful drive, and the regurgitation beneath the aortic column permits of its rapid recession; and we have the phenomenon of the "subungual pulse." This is not a manifestation of rheumatism of the skin, but it is a cutaneous manifestation of rheumatic endocarditis.

The nails themselves undergo a marked alteration in those afflicted with the rheumatic "diathesis." They become brittle and striated, the markings taking the longitudinal direction. It is prudent for those who note this abnormality to take stock of their general condition, and avoid the confirmatory agony of acute arthritis. It will be found as a rule that nails of this description are associated with the plethoric picture of "lithemia."

Sudamina are minute vesicles occurring in the course of conditions marked by free perspiration. They are supposed to be filled by droplets of sweat. It is a remarkable circumstance that here, as in the disease of the hands and feet known as dysidrosis or difficult sweating, there should be an associated hyperidrosis or excessive sweating. However this may be, it is a fact that rheumatism, signalized by drenching perspirations, is also complicated by the occurrence of sudamina. These sudamina often result in a punctate dermatitis whence the transition to a punctate eczema is easy and natural. Here we have an exemplification of the direct etiological connection between an acidosis like rheumatism and the commonest of fatherless dermatoses.

Intertrigo is an affliction whose obstinacy is a source of the keenest disappointment to both patient and physician. It is ascribed to the irritation incident to the friction of overlapping cutaneous surfaces. This is usually regarded as the last word on the etiology, and frantic and unavailing efforts are made to cure it along that line. Our failures are attributed to the carelessness of the patients or to anatomical conditions that are irremediable. For is not intertrigo commonest in the obese flabby sort of individual with great masses of pendulous tissue? The elephantine female, with mighty mammæ sprawling on a paunch of portentous proportions, gross, grotesque and greasy, is the favorite victim of this exasperating dermatosis. This description of the conditions favoring the development of intertrigo would seem to be a confirmation of the general opinion regarding it.

But that does not tell the whole story. This blubbery behemoth is the product of a long course of inordinate eating, drinking, and inactivity, all tending to the nutritional abnormality known as acidosis. Such a creature in the phraseology of a past generation would be called "lithemic," would be said to have the rheumatic "diathesis." The furred tongue, high-colored urine, and sour perspiration would be adduced in support of this contention. The lithemic were also subject to vague attacks of myalgia, neuralgia, and cephalgia. Their metabolism was assumed to be so disturbed as to tend to the precipitation of stony particles in the kidneys; hence the designation lithemic. The older pathologists were not so far awry at that. The tendency to stone is favored by the dietary offenses that excite acidosis. The remedy was the reduction of the disturbing ingesta and the administration of alkalies in liberal amounts. A pretty accurate imitation of the method employed to-day to combat acidosis! It is a fair deduction that the irritated oozing skin between the overriding fleshy masses, is not due to the mechanical element alone but to that plus the presence of a highly acid and mordant perspiration. The treatment by local measures, no matter how skillful, varied, and persistent, will be unprofitable if the "lithemia," the "acidosis," the rheumatic "diathesis" is not controlled and the acridity of the perspiration reduced. It is objected that babies suffer from intertrigo and to them the foregoing strictures will not apply. It is wise not to run ahead of our horses. Babies *do* suffer from intertrigo, usually from contact with irritating

urine. But *all* babies do not have intertrigo even among those who may be carelessly handled and allowed to lie in wet diapers for quite extended periods. Babies have intertrigo for the same reason exactly that adults have it. They suffer marked metabolic disturbances from improper feeding, as is a matter of general information. It will be noted that the baby least prone to this sort of cutaneous disorder is the baby fed at the breast of a rationally nourished and healthy mother.

From intertrigo to eczema is a natural and easy transition. It is often effected. I realize that an attempt to establish a rheumatic etiology for eczema would be greeted with a chorus of derision. The whole problem is in such a condition of uncertainty that another hypothesis would be an added aggravation. But there are some facts that stand out with tolerable clearness, and it is permissible to push them to their logical conclusion. To begin with, eczema is a dermatitis always caused by an irritant. The irritant may be mechanical, chemical, or thermic, operating from without. It may be metabolic, operating from within. We are all familiar with the bartender's hands; the washerwoman's hands; the bricklayer's hands; the dyer's hands. We know the effect of the winter's cold on *all* our hands, and of a strong east wind upon our faces. But we are all more or less possessed of the notion that some people are predisposed to eczema; that it is in their blood and responds to irritations that would be ineffective in others. This idea is based upon the undeniable development of eczema without detectable external excitation, and following the injudicious indulgence in certain dubious ingesta. This does not indicate that the patient has a predisposition to the dermatosis, but that he has aroused an irritant within himself that attacks the skin from the blood stream. It will be found that the dietary indiscretions that bring about an eczema are the same as those that bring about an acidosis; that would contribute to lithemia if the term were still respectable; that will in fact favor an outbreak of rheumatism. Beer, wine, whiskey, heavy meats, and made-up sweets will be found provocative of both diseases. As in rheumatism so in eczema the amount and quality of the nutritional intake must be carefully regulated. The acid-forming components, either such as are too highly nitrogenized and produce metabolic disturbance, or those whose indigestibility arouses intestinal putrefaction, should be absolutely interdicted. Cathartics, especially the saline, are indicated. And—be it carefully noted—alkalies are to be freely prescribed. The combination of an alkali with the "blood medicines" for eczema is a routine procedure. The value of alkalies in rheumatism is reduced to a dogma. Furthermore the oozing so distinctive of eczema, is of "gluey" consistency and stiffens linen. This is a quality peculiar to colloid solutions and indicates plainly that the eczema is a colloid tumefaction excited by the presence of an acid irritant, in other words an acidosis. The foregoing reflections must be taken for what they are worth. It is difficult to construct a convincing argument upon analogy. Nevertheless it is often prolific of valuable suggestion enabling us to devise many a helpful expedient.

Pityriasis rosea, with its tinkling title and its picturesque plaques of salmon pink, is the subject of controversy among dermatologists, some upholding its rheumatic origin and others ascribing it to a parasite. The Germans take the latter view and call it herpes tonsurans maculosus. While grievously sinning against euphony they have failed to demonstrate the parasite. They reason from the circular and oval conformation, and the delicate scaliness of the surface. The contenders for the opposing view point out the efficacy of the salicylates whether supplemented by external medication or not. It is an insignificant malady at the worst and derives a fictitious importance only from the alarm experienced by the patient on discovering it.

Erythema scarlatiniforme has been responsible for many erroneous diagnoses of true scarlet fever. The likeness has been intensified by the occurrence of arthritic pains in the lesser malady and its termination in desquamation. The fact that scarlet fever is frequently complicated by articular rheumatism lends plausibility to the contention that the arthralgia and efflorescence in erythema scarlatiniforme are of rheumatic origin.

In the very acute attacks of inflammatory rheumatism the skin is liable to take on a sudden evanescent erythema. The superficial circulation is disturbed. This is noticed when the surface is exposed to the air. It is a curious phenomenon, somewhat akin to that observed in meningitis.

The obscurity surrounding the origin of herpes zoster is impenetrable. We can hazard a surmise but we cannot substantiate it. Like every other human ill to which we have no clue we would ascribe it to a microorganism. There is no evidence of this whatever. It is pure assumption. No germ has been found. The discrimination of the supposititious germ in selecting one particular nerve root out of so many for the exhibition of its pernicious activity is amazing. In fact it is incredible. Roving all over the spinal column seeking an opening for its mischievous intrusion it picks out one root from sixty-two and ever thereafter ignores the rest. The rheumatic hypothesis in the eyes of its opponents would appear to call for the same sort of criticism, for does not the rheumatic active agent, if a germ, display just as incredible penetration as the one we are "supposing?" And if it is a product of faulty metabolism, how is the explanation furthered? Somewhat in this way. In the one instance we are supposing a germ endowed with the wonderful faculty of selecting one nerve root for assault and never thereafter accomplishing any pathological purpose. Whereas under the rheumatic hypothesis the cause includes that nerve root in its general depredations, and may go on to an invasion of the joints or the heels or the sciatic nerve. It has been objected that as herpes zoster never recurs it is not of rheumatic lineage. The implication and the direct assertion are both wrong. Herpes zoster sometimes recurs. And erythema nodosum admittedly rheumatic, recurs but very rarely. The singularity of the lesion in zoster is matched by the sigularity of the lesion in mitral stenosis, by the singularity of the lesion in torticollis and in rheumatic iritis. It will not do to discredit the intimated etiology by an argument based on the number of lesions, as this would eliminate many undeniably authentic conditions. The causes immediately exciting an attack of zoster are those credited with the excitation of rheumatism. Dampness, cold, and sudden closing of the sweat glands would appear to be culpable in both instances. In herpes zoster salicylate of sodium is as dependable an analgesic as any other.

It is manifestly impossible to *prove* the etiological relation of rheumatism to any of these diseases of the skin. Until we can isolate its essential cause, until we can settle the dispute between the sup-

porters of parasitism and deranged metabolism, we are in no position to make any authoritative pronouncements regarding its alleged pathological fecundity. We may, however, rationally argue from experience and analogy as to the probabilities, in many conditions reduced to the level of certainties by the accumulation of evidence. It is incontrovertible that rheumatism causes endocarditis.

The sequence of events is so uniform here that no one dreams of questioning it. Yet rheumatism is not the only cause of endocarditis and not all cases of rheumatism are thus complicated. Yet it occurs so often in connection with rheumatism that the association has become assured. Purpura has been ascribed to the same cause as we have already seen. But exactly paralleling endocarditis, all cases of purpura are not rheumatic. Some are scorbutic, some are pyemic, some are anemic, some are luetic. But the general run are rheumatic. Erythema nodosum, likewise, is placed in the rheumatic category for no better reason than its occurrence in persons showing other symptoms of rheumatism, at or preceding the time of attack. It is a matter of induction from many instances and of analogy between concurring conditions. It is as fair, then, to suggest the probability of a rheumatic etiology for some of the other rare dermatoses such as herpes zoster or for some of the commoner ones of undetermined origin, such as eczema and intertrigo.

If we will shift our ground a bit, and for the term rheumatism substitute the term "acidosis," we shall see the situation in a more convincing light. Whatever the opinion held as to the origin of rheumatism, there is unanimity regarding its producing an acidosis. And an acidosis will account for any of the dermatoses we have been discussing. The transcending importance of this conception lies in its therapeutic application. Irrespective of the pathological initiative, disregarding for the nonce the academic differences relating thereto, we have hold of a great truth pregnant with tremendous possibilities of evil if ignored, and of comfort and satisfaction if zealously pursued. This may sound like hyperbole if taken in reference to diseases of the skin, but they constitute only one phase of the subject of acid intoxication, which in its entirety comprises the weightiest problems of the conservation of human health. But even in the restricted and little heeded field of dermatology much misery may be averted by a painstaking attention to the principle involved; for be it remembered that the heartache and economic loss of an acne may be as serious to its victim as the pangs of acute arthritis; that the physical distress of a persistent pruritus may be as nerve-racking and health-wearing as a high pressure cephalalgia. Work is lost because men must scratch. Sleep stares in grim mutiny, because of the work that is lost, and the itch that is not. Health slumps; "reason totters on her throne." Is that overdrawn? Ask any of the itch-bedeviled, and note the soulful emphasis with which he will tell you that he would sooner be dead than continue as he is! Can any of the "important" pathological conditions with which practitioners are so deeply concerned produce a more desperate dejection than that? From every angle then (even that of dermatology), there is no more fascinating, fruitful and remunerative subject of investigation than *acidosis*.

IODIDE OF POTASSIUM IN SYPHILIS.

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO.

Many circumstances have contributed to the neglect into which iodide of potassium has recently fallen. Chief among these are the introduction of salvarsan in the treatment of spyhilis, the elaboration of more efficient methods of giving mercury, and a very general desire to explain the undoubted good effects of the iodides on gummata, arteriosclerosis, and aneurysm solely by their action in increasing the secretion of the thyroid gland. Furthermore the general recognition of the fact that the iodides are not spirocheticides has added to this neglect or even antagonism, for there are those who are antagonistic to their employment in syphilis at all. These people are often afflicted with the idea that a disease in order to be treated must be killed out, forgetting entirely the great truth that often the management of a malady, or an oblique action on it is of much more importance than its annihilation. Granting that the iodides as administered are under no circumstances detrimental to the life of the invading spirochetes, and this is by no means certainly true, there is no clinician, even of moderate experience, who has not repeatedly seen wonders performed by them, and none of us can afford to grow so saucy toward that great disease syphilis as to despise, in its treatment, any friend however humble, and iodide of potassium, as an antisyphilitic is by no means humble.

Iodide of potassium is particularly valuable in tertiary syphilis, whereas mercury and salvarsan are effective in all stages of the disease, undoubtedly in a great measure because of their spirocheticidal power. The use of one or two of these drugs, however, does not preclude the employment of the third, and as a matter of fact, when thought advisable, all three may be given.

That iodide of potassium has no particular value as an anti-syphilitic in the early stages of lues should not carry with it the assumption that it is altogether useless in this stage. As Scholtz says, it often has an excellent influence on the prodromal symptoms, such as fever, headache, and pains in the limbs, in which case it is given in moderate dosage, eight to fifteen grains (0.50-1.00) three times a day.[1] Its good effect in such an eventuality is no light matter. I have seen the headache of this early stage assume such proportions as to lead the patient, a physician, to seriously contemplate suicide.

It used to be customary to give the iodides after a course of mercury with the idea that the iodine, by chemical selection, would pick up the mercury, and carry it out of the body. With this belief of the union of the two metals in the body and the prompt exit of the pair, there often was associated a notion that mercury when not so accompanied, was tardy in passing along, and lingered especially in the bones. One now scarcely ever hears this view expressed. Indeed mercury leaves the body with remarkable speed in any event, and it is doubtful if anything but diaphoretics, diuretics, and laxatives can accelerate its departure. As, however, the iodides powerfully stimulate secretion and excretion, they aid in this way the elimination of mercury and any other foreign matters present in the body.

The specific therapeutic effect of iodide of potassium can be seen in gummatous, highly proliferative

cutaneous lesions, which often melt away under its use as if by magic, and it is important to note that this diminution in the bulk of the lesion in question occurs without any previous swelling. The importance of this lies in its contrast with the action of salvarsan, with which a preliminary congestion and swelling takes place. In a lesion in the nervous system, for instance, this preliminary congestion and consequent increase in size may precipitate an impending misfortune that might easily have been averted by giving first a few doses of iodide of potassium. Furthermore it is well known that luetic lesions of the nervous system are often directly connected with the blood-vessels, and rightly or wrongly clinicians for years have attributed to iodide of potassium an easing influence on arterial tension, and a beneficial action on the blood-vessel walls. These effects, however, may be entirely from increased general chemical action and increased secretory activity, which has already been mentioned and which will again be considered.

These three effects—the prompt diminution in the bulk of the syphilitic tumor, the possible easement of the blood pressure, and the effect on the vessel walls are not the only ones that interest the nervous system. From the by-effects of a drug may often be gained an idea of its usual mode of action.

Sometimes, for instance, iodide of potassium violently stimulates the nervous system, causing tremulousness and tachycardia, with or without swelling of the thyroid gland. In fact these symptoms are attributed to hyperthyroidism induced by the drug. I know a physician, who, on taking a rather stiff course of iodide of potassium for an opacity of the vitreous, had the satisfaction of seeing the mote disappear, but got tremulousness of the hands and a racing heart that kept him in bed for some months. The tremulousness has remained with him. These rare instances of overaction probably indicate one of the usual effects of iodide of potassium. By stimulating the thyroid gently it increases oxidation and general metabolism, and therefore increases the body capacity for oxidizing and eliminating both the cause and the products of disease.

To show how various the honest opinions may be in regard to the value of iodide of potassium I shall relate a conversation with the late John F. Morse, a man of eminently independent judgment. He said he would be in despair should he acquire syphilis, as he had a well marked idiosyncrasy toward iodide of potassium, and he was convinced mercury in this disease was valueless. The probable way he arrived at this conclusion is interesting.

Doctor Morse's chief experience at that time was gained in the County Hospital, where he had under his charge a large number of poor faint souls past corporal toil, who could not by any means be induced to undertake the labor of inunctions. As the technique of deep subcutaneous injections was not then developed, mercury had to be, in such a case, administered by the mouth, now admittedly an inefficient method. Furthermore the kidneys of these old sclerosed people were sensitive to mercury and poor eliminators, so that an efficient dose would often react badly on their general health. On the other hand their late gummatous proliferative lesions were particularly susceptible to iodide medication, and their sclerosed arteries and fading thyroid would also be favorably affected by the drug. In all probability a prolonged course of iodide of potassium at moderate dosage would be better for these old people than a thoroughgoing spirocheticidal course of mercury and salvarsan. The physician's attitude toward drugs, however, should never be partisan as that of an advocate or a politician, and a recognition of the merits of iodide of potassium should not carry with it the denial, even to such patients, of the benefits accruing from a judicious use of either mercury or salvarsan.

Iodide of potassium has no effect on the chancre, on the adenopathy, or on the eruptions of early constitutional syphilis, or on many of the eruptions of late syphilis, nor has it the power to change the Wassermann reaction from a positive to a negative. These facts must be regarded as good proofs that it is not a spirocheticide, or at least not one of great potency.

There is no doubt, however, that iodide of potassium exerts a most profound effect on the patient's physiology; its numerous striking, sometimes even dramatic, by-effects show this. Iodic catarrh and iodic acne are almost always present even with a moderate dosage. The frequent occurrence of purpura shows the effect of the drug on the blood and blood-vessels, and its influence on the thyroid gland, and through it on the circulation and on the nervous system, has been mentioned.

In organic chemistry iodine is one of the most important elements in making the various synthetic preparations, and it may be equally important in the chemical changes within the body. As a halogen it is nearly related to chlorine, and this relationship is well seen in its substitution of chlorine in animals which are deprived of NaCl, and given instead KI or NaI. In animals so fed the gastric glands secrete hydriodic (HI) instead of hydrochloric (HCl) acid.[2] The manner in which secretions loaded with iodine act in regard to calomel is also instructive, and may have a bearing on this very question. In such a case calomel ointment must not be prescribed in any situation where it may come in contact with the urine, nor may calomel powder be dusted into the eye, as in either case the extremely caustic biniodide will be formed. It would seem that under these circumstances the iodine has such a strong affinity for the Hg that it is able to supplant the Cl, so forming HgCl. It may be that some such chemical affinity is responsible for the speedy way some of the syphilitic neoplasms melt down under the influence of iodide of potassium.

From the other various preparations of iodine much may also be learned of the action of this important drug. One might imagine that iodide of sodium would be more effective than iodide of potassium, as the iodine in it is linked up with a metal sodium, that is much more abundant in the body than potassium, and also because it contains about 10 per cent. more by weight of the active ion, iodine. As a matter of fact, however, iodide of sodium is less active therapeutically than iodide of potassium, and although it has a much less disagreeable taste, has never been nearly such a favorite with the medical profession, which is a point in showing how fundamentally correct clinical opinion is apt in the main to be.

Iodide of strontium is a favorite with some, as they imagine it acts more favorably on the kidneys.

As all these three salts have probably different rates of absorption a mixture of them may attain the circulation in a steadier and more even stream

than any one of them alone. It may be this that accounts for Scholtz and others prescribing simultaneously two or three of these salts rather than one.

Iodide of rubidium acts well, and has few by-effects, but it is expensive.

A suspension of iodoform in liquid paraffin (1 c.c. of a 10 per cent. mixture) has been used, but has never become a favorite. It is said to be not unbearably painful, and acts fairly well, but it is apt to give rise to iodoform poisoning, such as skin eruptions, persistent subjective taste and smell of the drug long after its discontinuance, toxic amblyopia, and acute thyroid symptoms, such as rapid pulse, delirium, headache, vomiting, and fever. Short draws attention to the fact that these symptoms correspond exactly with those seen after the administration of excessive doses of thyroid extract.[2] From the persistence of the specific taste and smell of iodoform it might be inferred that the CHI_3 does not break up and leave the body, but either continues to circulate in the blood or remains in the thyroid gland, continually inciting it to increased production of iodothyrin.

Short further states that he has found thyroid extract quite as effectual as iodide of potassium in healing tertiary syphilitic ulcers.[3] That thyroid extract may influence a luetic lesion favorably is quite probable, because a principal constituent of it is iodothyrin. I, however, do not believe that it would act as energetically as iodide of potassium. Furthermore, anything like an effective dose should give rise to hyperthyreosis.

It may be that the secretion of the thyroid accounts for one of the most interesting phenomena of lues, the comparative immunity of women from the graver neural forms, such as tabes and general paresis. The factors entering into this view would be:

1. The thyroid is more active in females than in males, as shown by the frequency of its enlargement in females, and by the much greater number of cases of Basedow's disease in females than in males.

2. A principal constituent of thyroid secretion is iodothyrin.

3. All the iodine compounds exert a marked influence on syphilis.

4. The influence of iodothyrin, although small, would be exerted continuously and for a long time, and it must be remembered that some of the greatest phonomena in nature are produced by small causes acting through a long time.

5. The course of syphilis and especially of neural syphilis is very different in men and in women, and this difference may be due to the greater activity of the thyroid in women, especially so modifying the virus that it does not affect the nervous system.

Iodopin is a 10 or 25 per cent. chemical combination of iodine with the unsaturated fatty acids of oil of sesame. Its great advantage lies in the fact that it can conveniently be introduced subcutaneously. It has been now a long time in use, and has maintained its position.

As regards iodide of potassium the medical profession seems to be passing through an interesting period of therapeutic history. The newer methods of giving mercury, the brilliant effects of salvarsan, and the delicate check on the results of treatment afforded by the Wassermann reaction have aroused a great deal of interest and enthusiasm. The enthusiasm in regard to the physiology of the ductless glands and especially of the thyroid has also had, as has been shown, its effect on the attitude toward the therapy of the iodine preparations. Many men, however, express their enthusiasm not alone by being positive toward the object of their love or choice but by being strongly negative toward everything else. This temperamental attitude is to be deprecated in the practice of medicine.

ARTERIAL TENSION IN CONNECTION WITH CARDIAC MURMURS.*

By PAUL E. TIEMANN, M.D.,
NEW YORK.
MEDICAL SUPERVISOR, NEW YORK LIFE INSURANCE COMPANY.

Applicants for life insurance often present themselves for examination quite unaware of any cardiac abnormality, and again they may state that they have had a murmur for years but have never experienced any symptoms whatever. In fact in the great majority of cases where there is an unmistakable lesion it is evident that compensation is well maintained. Therefore the following observations, based on personal observations made at the home office of the New York Life Insurance Company, must be considered with special reference to life insurance examination.

In many instances diagnosis is difficult; thus we find a large class of cases in which the murmur is the only evidence of cardiac lesion, so-called, "functional" murmurs. Another large class is characterized by a systolic murmur at the base, which does not fall in the category of functional murmurs because of the intensity or distribution of the murmur, the force or the displacement of the apex beat, and so on, and in this article these murmurs are placed in the group, "Aortic Obstruction," though it is not claimed by any means that they are all cases of true aortic stenosis. Indeed Hirschfelder states that aortic stenosis is the least frequent of the lesions of the left side of the heart—5 per cent. of 1,781 cases of cardiac disease at Johns Hopkins.

In this report the attempt has been made to consider only uncomplicated cases of cardiac murmur. Other conditions which might have exerted an independent influence on the blood pressure have been excluded, such as albuminuria with or without casts, glycosuria, or a recent history of the same, pulmonary lesions, marked anemia, and so forth. Exceptions are three cases in the aortic regurgitation group, one with a few hyaline casts, and two where the analysis of the urine was not known.

The blood pressure was taken by the auscultatory method, the fourth phase being selected to determine the diastolic pressure. The instruments were the Tycos and the mercury manometer, the former being checked up with the latter from time to time to make sure that the two agreed.

F. A. Faught believes that in the pulse pressure there is a definite guide to the state of the cardio-

*Read at twenty-sixth annual meeting of the Association of Life Insurance Medical Directors of America.

vascular system which is more reliable than the systolic pressure alone. He claims that the normal relation between systolic, diastolic, and pulse pressures should be, D = 2/3 S. P = ½D., or a ratio of 1-2-3, and that if this ratio be maintained the resulting arterial compensation may be regarded as safe. Reference will be made later to this pressure ratio. From observations on twenty normal cases, from 22 to 53 years of age, Faught found the tensions as follows:

	Systolic	Diastolic	Pulse
High	155	100	55
Low	110	70	35
Average	125	85	43

This works out very closely on applying the 1-2-3 ratio to the average tension. Two-thirds of 125 = 83, and one-half of 85 = 42.

Functional Murmurs.—There were seventeen cases between the ages of 19 and 41. The average blood tension of these was:

	Systolic	Diastolic	Pulse
	126	76	50
By Faught's 1-2-3 ratio	126	84	42
or a practically normal tension			

Mitral Regurgitation.—In compensated mitral regurgitation the arterial tension is practically normal, according to Norris. Hirschfelder says the tension exhibits no characteristic features, and the figures obtained are the results of varying causes. At Johns Hopkins Hirschfelder found that 29 per cent. of the cases of mitral regurgitation were associated with aortic regurgitation, 21 per cent. with mitral obstruction. In this connection it may be pointed out that a high pulse pressure in mitral regurgitation may be indicative of beginning aortic regurgitation.

According to 1-2-3 *ratio*	144	96	48
Showing an increased pulse pressure. These figures are appreciably higher than Faught's average of	125	85	43

Aortic Obstruction.—In pure aortic obstruction both the systolic and the diastolic pressures are slightly increased, partly due to the hypertrophy of the left ventricle, partly due to the general arterial sclerosis. The pulse pressure is small. (Norris.)

In aortic obstruction Hirschfelder says that tension is slightly elevated, a maximum of 130 to 160 systolic, partly due to the accompanying arteriosclerosis, partly to the increased intraventricular pressure.

Bearing in mind what was said in the beginning about the class of cases enumerated under the head of aortic obstruction, the following table of pressures is submitted:

Tension in 50 Cases of Aortic Obstruction

	Ages:	Below 20 5 Cases	20 to 30 22 Cases	30 to 40 10 Cases	40 to 50 8 Cases	50 to 60 5 Cases

	Low	40	35	35	40	25
	Average	54	58	57	59	44

	S.	D.	P.
Average for all ages	135	79	54
Not far from the 1-2-3 ratio of	135	90	45
Or from Faught's normal average of	125	85	43

Aortic Regurgitation.—Aortic regurgitation is characterized by a greatly reduced diastolic pressure, at times only 30 to 40, where the normal is 90 to 100. Schwarzman says he is greatly impressed with this phenomenon, and when he finds such a low diastolic pressure he makes the diagnosis of aortic regurgitation even when no murmur exists, and the subsequent course of the case justifies this view.

According to Norris, in aortic regurgitation a high pressure is often seen with good compensation; thus, a systolic pressure of 180 to 200 should not be regarded as hypertension. In estimating the diastolic pressure the fourth phase, or muffled sound, must be chosen, since the fifth phase sometimes persists down to the zero of the scale.

In aortic regurgitation Hirschfelder describes two groups of cases, one the endocarditic, where there is a considerable fall in the minimum pressure, as for example, S. *150*, D. *50*, and second, the arteriosclerotic, where there is a considerable rise in the maximum pressure, as S. *170*, D. *90*.

The distinguishing feature of aortic regurgitation, therefore, is the constant high pulse pressure. Where the murmur is present but the pressure is near the normal it is probable that the leak in the valve is small.

Norris says aortic regurgitation may exist without an audible murmur, or the murmur may be low-pitched and difficult to hear. Thus, Jackson in 100 autopsies found that this was the most frequently overlooked of the valvular lesions.

The following table comprises cases of simple aortic regurgitation and of aortic regurgitation with other valvular lesions. The tension of each individual case is first given.

Mitral Obstruction.—In compensated mitral obstruction the tension is more frequently above than below the normal; the pulse pressure is small. (Norris.) Faught says the blood tension may be low because only a portion of the normal amount of blood can be forced into the left ventricle. Only eight cases were observed, but the figures are presented as they may be of interest:

TRAUMATIC HYSTERIA: TRAUMA THE CAUSE OR OCCASION?*

BY DANIEL B. HARDENBERGH, M.D.,
MIDDLETOWN, N. Y.

IN twenty-five years of medical study and practice I have witnessed one change in medical teaching in regard to a somewhat numerous group of cases, and believe that there is now in progress a second. This group was earlier designated "railway spine," and more recently "traumatic hysteria."

Early in this period the teaching of Dana and others was gradually supplanting the theories of Erichsen that the condition had an underlying basis in pathological changes in the spinal cord.

Though the condition is now recognized as a psychosis, the cause is ascribed to trauma, physical or psychic. That the condition is strictly a psychosis rather than a neurosis seems to have been readily admitted.

That the essential cause of the cases of true hysteria occurring in these circumstances is suggestion, and not trauma, is a conclusion at which I arrived after examination of a considerable number of cases. I say true hysteria because the group is fringed by many instances where simple malingering is the predominant feature, and by some instances where actual organic injury has been sustained.

When I reached this conclusion I had not read Babinski or his followers. I might now present the points I wish to make by an extended study of their writings, and a recapitulation of their teaching, but choose rather to approach the matter from the standpoint of my own experience and reflections, believing that each member of this society will judge the soundness of the views expressed in much the same manner, in the light of personal experience.

Mrs. S.—Forty-six years old. While sitting in a railway station the single-piece moulded back and seat of the bench gave way and dropped a few inches. It was constructed low and did not drop far enough to reach the floor. She said she was dazed, and walked out of

*Read at a meeting of the First District Branch of the Medical Society of the State of New York, October, 1915.

the station; that her husband brought her back in the station, and that later she walked home. That night she complained to her husband of pains in the back and of nausea. Two days later pain in leg and arm began, and she called a physician. The pains gradually increased, and she lost strength in the legs and back so that she could not rise up in bed. Had contractures at knee and could not use left arm. Nausea persisted and control of bladder was lost, continuing for five or six months. Her claim against the railroad company was in the hands of an attorney, who was instrumental in having her removed ten months after the accident to the Neurological Institute in New York City for treatment. At that time she had not stood since early in the period following the accident. Her right arm she used in feeding herself, but her left was apparently powerless. Sight and taste were impaired; also hearing in left ear. She complained of diplopia. My examination was made two months after her admission to the hospital. She had made steady improvement since the first week. By pressure of reassurance and firm compulsion on the part of her physician there she had come to stand and to walk, exhibiting paralysis of no group of muscles, but rather the "I cannot will" of the hysterical. Physical examination revealed normal reflexes and absence of atrophies. Coordination hesitating but competent. There was a slight limitation of the field of vision in the left eye. The inability to move the left arm and leg, still claimed, gave way to persistent urging, and the limitation of movement was apparently due to action of opposing groups of muscles. There was an anesthesia of left side still claimed, but sensation was acknowledged in left scalp, and when arms had been crossed and the left hand and wrist were held against the right side of the body sensation was acknowledged in that hand and wrist. The anesthesia to pain was also superficial, deep thrusts revealing rather a hypersensitiveness. A physical stigma was noted in asymmetry of the arms, the right being 1⅝ inches longer than the left.

This case was free from many quite usual opposing claims and influences. There was no allegation by her physicians or attorneys that organic injury had been sustained. Nor from the opposing corporation was there denial of the diagnosis or contention that her physicians and attorneys had conspired otherwise than for the best interests of the subject.

With all the attending harmony, medical and legal, this case presents a remarkably clean-cut issue as to a fundamental point, the cause of the hysteria. That the woman must have had a neurotic tendency by reason of constitution or training, or both, will be admitted. What then was the determining cause of the hysteria—trauma or suggestion?

Was there in the sudden lowering of the seat upon which she rested, a fraction of a foot, sufficient physical violence to produce this chain of symptoms? That physical trauma in itself is not a satisfactory explanation of the origin of hysteria is understood; and its origin has been attributed to the mental shock or psychic trauma. Well, was there in the sinking of the low seat in this waiting room part way to the floor enough of frightfulness or horror to produce this result?

We have but to review the frequent trivial mishaps that are of almost daily occurrence in the life of everyone, the noise at night that suggests an intruder, the skidding of an automobile, the unexpected extra step in descending a staircase, to find sources of alarm of equal magnitude with this occurrence. Yet in the relation of this history the details did not occasion surprise; not to this body, nor to the fellow citizens of the subject as the progress became known.

What are the conditions that characterize and explain the case? Simply that an injury has been inflicted, preferably, I should say slight, for which a great corporation is manifestly responsible. Preferably slight, because the contemplation of serious injuries sustained, such as the loss of limb, is found rather to exclude the development of hysteria.

Serious physical injury seems to be related to subsequent hysteria rather as a deterrent than as a cause, and we have remaining as a common characteristic condition merely an offending, responsible corporation; not a physical entity, but a chain of associated ideas. And what is more likely to explain as cause hysteria, which is defined by Osler as a condition in which ideas obtain such control of the mind as to produce morbid symptoms, as the introduction and adoption of certain associated ideas. It is not necessary to assume that the subject was coached or urged by the suggestions of surrounding friends.

That persons receiving slight injuries upon the railroad had developed a set of nervous symptoms in which paralyses and loss of sensation had figured prominently, that compensation in damages had been made for same, and that in the end recovery had usually followed, was common knowledge in the community where the subject resided.

That instances in which such claimants had been revealed to the public as malingerers had also attached a certain odium to such claims is also true. Among the better informed there was the knowledge that instances had occurred in which large sums had been awarded without contest, in evident sympathy, to be followed in turn by recovery.

With such knowledge implanted in one susceptible in constitution and education to hysteria, it needs no further external suggestion to institute, when opportunity knocks, a chain of ideas that are allowed to develop until the syndrome is established. If then a false idea is at the bottom of these cases of hysteria, it becomes the physician's duty to expose and sweep aside that pretense or delusion; not so much that justice may prevail, though that is a worthy motive, as that the sum total of mental and physical morbidity may be decreased and not fostered.

Whether, precisely, the delusion is that trauma, even slight, may cause a group of symptoms of disability or suffering, or, in its more venal aspect, that such a group of symptoms when exhibited after an accident will probably be followed by abundantly assuaging damages and subsequent recovery; in whichever form, the false idea is equally pernicious in results.

There is already a wholesome distrust that leads many to inhibit the development of these ideas, and to cast aside as venal and reprehensible all notion that the slight accident to which they were exposed will lead to nervous symptoms, and afford ground for heavy claims against some one. With them the hysteria does not follow. Not that the trauma has not occurred, but that the true cause of the hysteria, the adoption and nurture of certain ideas, has never occurred. In this newer concept of the causation of hysteria lies a distinct advance in preventive medicine. When the traumatism has been found by careful examination to have produced no organic injury to the nervous system, the subject may be most confidently assured. A half belief on the part of the physician in the theories of Erichsen, or that a slight traumatism may cause hysteria, can but be reflected in the mind of the patient and become an operative factor for harm.

Nor without an adequate examination can the physician have, or impart to his patient, the confidence that the absence of organic injury warrants. In the East, self-mutilation is allowed to become

a source of additional alms to the mendicant. Here such practice would not be tolerated. It is somewhat analogous that there is here also a popular lack of sympathy with hysteria, that is at bottom wholesome, just, and salutary. The physician in his better understanding of hysteria should develop neither a fostering sympathy nor an unfounded apprehension of it.

As physicians we are not particularly interested in the financial problems of corporations; but it is well, perhaps, to note that there is one way to acquire responsibility for hysteria following trauma, and that is by assuming it. What greater contribution to the linking of the concepts of slight accident and subsequent nervous phenomena than the recognition of causative relation by those whose duty, if compatible with justice, is to dispute it?

In conclusion permit me to repeat that it has been my personal observation of traumatic hysteria that the frequency is rather inversely to the shock received. That the trivial character of the trauma, in many typical cases, and consideration of the comparatively few instances where grave injuries are followed by hysteria, make trauma an unsatisfactory explanation of the cause.

On the other hand suggestion is a natural explanation of such a condition as hysteria, and the association of the ideas of slight injuries by corporations and the development of paralyses and loss of functions is sufficiently common to be present in the average subject, and if it is on occasion of the injury entertained and fostered, it is capable and of a character to produce the symptoms of hysteria.

7 Orchard Street.

ETIOLOGY OF PELLAGRA.*

By B. W. Page, A.B., M.D.,

Lumberton, N. C.

Since July, 1912, I have observed in more than 600 specimens of feces from 158 cases of pellagra an actively and progressively motile, cell-like body that develops into a bacillus which at first is very active. It rolls, turns summersaults, spins, and darts across the field but soon reaches a state of rest and later presents a beaded appearance. The size of the organism varies greatly. The oval form ranges from .5 to 1.5 microns in diameter. The rods vary from 2 to 6 microns in length and .5 to 2 microns in diameter. On agar it grows primarily as a coccus. On a special medium containing 2 per cent. each of beef extract, dextrose, corn, and potato with one and one-half times the usual amount of peptone it assumes the form of a bacillus. End spores are noticed in all cultures from 2 to 6 weeks old. The organism has a capsule barely visible, sometimes forming a halo. It stains with the common aniline stains for bacilli. Loeffler's alkaline methylene blue stains the organism very quickly.

Some cultural characteristics of the organism observed by me and confirmed and further tested by Prof. B. F. Kaupp of the North Carolina Experiment Station are as follows:

Corn Agar Plate.—A twenty-four hour colony measures from 1 to 2 millimeters in diameter. The surface is convex. The borders are smooth. The color is whitish gray. Forty-eight hour colonies are umbonate and measure 3 millimeters in diameter.

Corn Agar Slant.—At twenty-four hours the growth is abundant. Form, aborescent; elevation, raised; luster, glistening; topography, smooth; optical characters, opaque; chromogenesis, grayish with age; odor, slight and apparently characteristic of the organism; consistency, a tendency to be slimy; medium not effected.

Corn Agar Stab.—At the end of twenty-four hours there is apparently no growth along stab line. Surface growth abundant and same as for corn agar slant.

Potato.—The twenty-four hour growth is abundant. Surface rough and pitted. At the end of three days at incubator temperature the surface takes on a light tan color and growth covering surface has an areolate appearance. Luster, dull.

Bouillon.—Scum on surface. Bouillon not clouded at end of forty-eight hours. Heavy precipitate in bottom of old cultures. Scum wrinkled in old cultures.

Two Per Cent. Dextrose Agar Slant.—The twenty-four hour surface growth is abundant with tendency to spread over entire surface. Edges, smooth. Line of puncture not closed and growth moderate and echinulate.

Milk Inoculation.—At the end of twenty-four hours the milk is not coagulated. Slight separation of surface whey. Cultures of forty-eight hours and older show digestion of casein. Delicate membranous surface growth. Contents of tube examined after one week's time and no acid present. Medium at end of week still neutral to slightly alkaline.

Gelatin, Plain.—Stab, where stab line closes there is no growth below the surface. At the end of 24 hours at a temperature from 85° to 90° Fahr., there was a slight whitish growth at the surface but none along the needle tract. Growth continues till entire surface is covered, which is about three or four days. There is slow liquefaction of stratiform character and finally after about ten days a scum-like growth.

Two Per Cent. Each, Beef Extract, Dextrose, Corn, Potato.—Twenty-four hour growth, no scum on surface. Bouillon clouded. Heavy precipitate in bottom. Scum appears on surface in two to three days and becomes wrinkled in older cultures.

Two Per Cent. Beef Extract, Dextrose, Corn, Potato, Agar Slant.—Twenty-four hour growth very abundant, covering entire surface and extending more deeply into medium.

Two Per Cent. Dextrose Bouillon.—Fermentation tube, growth abundant at end of twenty-four hours in unclosed arm. No gas formed nor growth in closed arm. At end of forty-eight hours still no growth in closed arm. Apparently aerobic as there was a plain line of demarcation at commencement of closed portion.

Two Per Cent. Lactose Bouillon in Fermentation Tube.—Same results as in bouillon fermentation tube.

Two Per Cent. Saccharose Bouillon Fermentation Tube.—Same as in dextrose bouillon fermentation tube.

One Per Cent. Saccharose Agar Stab.—Needle tract did not close entirely and at the end of twenty-four hours showed a slight echinulate growth along the needle tract. Abundant surface growth spreading over entire surface.

One Per Cent. Saccharose Agar Slant.—A twenty-four hour growth was spread over entire surface. Tendency to be aborescent. Otherwise the same as corn agar slant.

One Per Cent. Lactose Agar Stab.—Same as corn agar stab.

* Read at a meeting of the Robeson County, N. C., Medical Society.

One Per Cent. Lactose Agar Slant.—Same as corn agar slant.

Search for the Organism in Normal Stools.—Only six normal stools have been plated out for search for this organism, but the organism was not found.

The organism seems to be pathogenic for the following reasons: *First*, it proves to be constant in the stool while definite symptoms of pellagra exist. It has been isolated from stools of three pellagrins three different times. It has been isolated from one specimen from each of thirteen other patients suffering from pellagra. I am convinced that I have observed the organism in more than 600 specimens of feces from 158 pellagrins since July, 1912.

Second, the organism in pure culture when fed to mice produces a toxin that causes death in twenty-four to ninety-six hours. Those that die early seem to die of septicemia. Those that live three or four days seem to die from general weakness and emaciation. The organisms are found in all the organs after death. Pure cultures have been obtained.

Third, blood serum from pellagrins as a rule has very little effect on the organism. In very severe cases with high fever the blood serum occasionally gives a positive widal reaction. Serum from natural blisters occurring on pellagrins and serum from blisters produced from cantharides plasters renders the organism non-motile and agglutinates them in three to thirty minutes in a mixture of the serum with an active culture in proportions of 1 to 5, or 1 to 10, or even 1 to 50. Similar tests were made with typhoid and colon bacilli with negative results. Serum from blisters of healthy individuals gives negative reactions with all these organisms. Serum from blisters of a pellagrin agglutinates the organism from the same patient and other pellagrins also.

Fourth, one of the several healthy persons previously examined with negative results, after accidental exposure in a laboratory, developed symptoms of grippe which later proved to be pellagra. The organism was isolated from the stool on the third day after symptoms developed. The organism was again isolated from the stool eight and twelve months later. Symptoms of the disease still exist.

GASTRIC SYMPTOMS IN TUBERCULOSIS.

By LOUIS HENRY LEVY, M.S., M.D.,

NEW HAVEN, CONN.

THE simultaneous occurrence of symptoms of gastric disturbance and tuberculosis is becoming more recognized now that the *x*-ray has been added as an aid to diagnosis. The complaint of symptoms of gastric disturbance has often tended to make the examiner focus his attention to the supposed seat of the trouble—the stomach—and to overlook entirely or to examine less carefully other organs. The recognition of the fact that chronic conditions of the gall-bladder, of the appendix, of the heart and kidneys, often by reflex action or by congestion, set up a disturbance of the stomach, has brought these organs into the field of examination more than formerly. But that tuberculosis, whether of the lung or whether of an intraabdominal nature, may be an important factor in the production of gastric symptoms, has neither been fully appreciated nor forcibly enough impressed. At times it may be difficult to properly examine the patient for lesions in organs other than the stomach, but in chronic cases with gastric symptoms a complete examination should be insisted upon, in fairness to the patient as well as to the physician. One will be surprised to discover the many cases in which there is a definite lesion in the lung without pulmonary symptoms being present.

Of course one must bear in mind that lesions in the stomach may exist independently with a pulmonary process and bear no relation to it; and it must also be borne in mind that, when a patient presents himself with symptoms and signs of pulmonary tuberculosis and with only slight gastric disturbance, the gastric condition must not be thought simply reflex but that there may exist a definite gastric lesion which may require special attention and treatment.

The pulmonary lesion present may vary from the slightest involvement to a most extensive involvement with marked emaciation and anemia. There may be present only slight dullness at one apex, which later becomes the seat of a more extensive lesion. There may be present only an occasional click or an occasional râle brought out by coughing. There may be present a miliary condition or a massive consolidation with or without cavity formation. When the lesion in the lung is slight it may be difficult to explain the gastric symptoms because it does not seem entirely satisfactory to attribute them to reflex action. It is more probable that the symptoms are due to toxic elements liberated or produced by the tubercle bacillus. In the more advanced types with emaciation and anemia, the causes of the symptoms can be more readily understood.

Symptoms of gastric disturbance associated with tuberculosis may be produced in one of two ways: (1) Indirectly, without any changes in the stomach. (2) Directly, associated with organic changes in the stomach. When there are no changes in the stomach several factors must be considered. These depend first of all on whether the tuberculosis is pulmonary or intraabdominal and the stage of disease if pulmonary, that is, whether it is incipient, moderately advanced, far advanced or arrested. The presence of a miliary tuberculosis, consolidation or cavities also tend to alter the symptomatology. Hutchinson has stated that he has found gastric symptoms in 92 per cent. of cases of pulmonary tuberculosis which he had carefully examined. These findings have been corroborated by others (Dobell, Fenwick, and Pollack).

Fenwick has found that in a series of 500 cases of pulmonary tuberculosis that 72 per cent. of the females and 17 per cent. of the males had complained at some time or other previous to the discovery of the tuberculosis, of moderate or severe indigestion. It has also been found that gastric symptoms are less common in miliary tuberculosis and more common in cases where there is a consolidation of the lung. In miliary tuberculosis the gastric symptoms usually appear at the onset of the tuberculosis. In cases with consolidation or cavity formation the symptoms may precede these or may only appear when the patient becomes emaciated and the symptoms being due to asthenia or anemia.

The symptoms that precede the discovery of the tuberculous lesion or that accompany the onset of the condition in the order of their frequency are pain, vomiting, and disturbance of appetite. Flatulence and constipation are also present in a large number of cases. The pain, according to Hutchinson, occurs in 92 per cent. of the cases. The pain

may be either dull or sharp. More often it is dull and it is usually referred to as a sense of pressure under the lower part of the sternum. The pain may follow immediately after eating. It may come on from fifteen minutes to two hours after eating, or in a few cases it may bear no relation to meals and may be persistent. The pain usually bears some relation to the acid condition and motility of the stomach, and these two factors depend on the stage of the disease whether the condition is incipient or advanced.

Cohnheim, citing several cases in which there were marked emaciation and anemia, states that these cases were characterized by a ptosis and that he managed to obtain splash sounds in all of them. Not in any of these cases, however, was there associated pain or vomiting. Louis has found that two-thirds of his cases showed signs of dilatation. Fenwick in a series of one hundred autopsies found that sixty-four gave evidences of a dilatation of the stomach. This dilatation may be explained in one of two ways. It is either due to an atonic condition of the stomach or it may be due to the excessive feeding which is sometimes urged on tuberculous patients. The dilatation often produces periods of severe attacks of vomiting that may last as long as two weeks. The dilatation may also result in a marked hypochlorhydria with resulting fermentation and eructation of gas. The dilated or atonic stomach almost always shows a delayed motility, and hence delayed evacuation of the stomach contents. In these cases there is also a tendency toward constipation. In the very rapidly progressing cases associated with a marked anemia there is also present a hypochlorhydria, but in these cases there may be a diarrhea independent of any tuberculous involvement of the intestine.

Cohnheim mentions cases of advanced tuberculosis in which there was present a hyperchlorhydria. Einhorn mentions cases in which a hyperacidity was found, but does not state how far advanced these cases were. It will be found, however, that most of the cases in which there is a hyperacidity are in the earlier stages of the disease. Fenwick finds a normal acidity present in only 45 per cent. of the cases in his series. Of these 66 per cent. were cases with consolidation and 34 per cent. with cavities.

Those cases where organic changes have taken place in the stomach may be divided into three groups: (1) Cases associated with a gastritis. (2) Those associated with either single or multiple ulcers. (3) Those associated with tuberculous granulomata.

Gastritides may be produced by the toxins from the tuberculous lesion eliminated through the gastric mucosa and acting on it. Fenwick found well-marked evidence of gastritis in eleven out of fifteen cases. The gastritis may be either acute or chronic. Louis describes a peculiar condition of the mucosa which he calls mamillation, where there are a large number of minute elevations arranged in the form of streaks near the pylorus. Sometimes the entire stomach may be involved. At times these elevations become very large and resemble polypoid tumors. This condition is probably a chronic inflammatory condition where there is produced a contraction of newly-formed fibrous tissue between the glands.

Tuberculous ulcers of the stomach or gastric ulcers associated with tuberculosis were at one time thought very rare. Now that the condition is better known more cases are being reported. Gossman states that he found indications of tuberculosis in 40 per cent. of the 5,900 autopsies between 1900-1912 at the Munich public hospital. There were signs of tuberculous ulceration in the stomach in only 0.31 per cent. of all the cadavers or 0.76 per cent. of the tuberculous cases. A tuberculous ulceration was found in the duodenum near the pylorus in five other cases and in another group of five cases there were ulcers both in the stomach and duodenum. There was chronic pulmonary tuberculosis in all of the cases and the gastric and duodenal lesions had not been diagnosed during life. The findings confirm the possibility of the infection being carried by way of the blood, the lymph, the mouth or by spreading from adjoining lesions.

As Gossman states, ulcerations may be produced in one of four ways.

1. They may be produced through the lymph channels from affected neighboring structures or from tuberculous peritonitis. This is the view taken by Dewey who has studied the literature very carefully.

2. They may be produced by ulceration direct into the stomach from neighboring tuberculous lymph nodes. Such cases have been reported by Clayton and Wilkinson and by Besnier.

3. Ulceration may be produced by the direct action on the mucosa by bacteria which have been swallowed: ulceration from this cause is not so common. It occurs when there is marked disturbance in the motility of the stomach, or where there is a hypochlorhydria with a markedly lowered resistance on the part of the patient. In the normal stomach, the acid secretion is usually inhibitory enough while normal motility prevents the accumulation of the bacteria with the formation of a resting place for them. At times a carcinoma may lodge the organism where they will grow. Lyle reports such a case and quotes several from the literature. In Lyle's case a gastroenterostomy was performed but the patient died later from a tuberculous peritonitis.

The fourth method in which an ulcer may be produced is by the action of the bacteria through the blood stream as in cases of disseminated miliary tuberculosis. Arloing produced ulcerations in the stomach and duodenum of animals by inoculating the tubercle bacilli into the blood stream.

The pathology of tuberculous ulcers is usually the same as that of the more common ulcers of the stomach. They may vary from the very small pin head ulcerations representing hemorrhagic erosions to ulcers two inches in diameter. From the cardia to the pylorus the mucosa may be found covered with small round ulcers several centimeters in diameter. These, however, do not extend deeper than the muscularis, but in some cases have gone to the serosa. The edges are sharp and at times undermined. No tubercles have been found in this form. This is the type found in children who have died from general tuberculosis. There may be a follicular ulceration with slightly raised edges, the ulceration hardly ever extending below the mucosa. Fox has found these in 12 per cent. of his acute and 18 per cent. of his chronic cases of pulmonary tuberculosis.

If in the light of the newer teachings as demonstrated by the *x*-ray, we are to consider the first part of the duodenum, the so-called duodenal cap, described by Case and others, as continuous with and part of the pylorus, the number of cases of

ulcer is increased. Moynihan quotes 41 cases of this nature, some of which were associated with ulceration of the small intestine. Most of these ulcers have raised irregular thickened edges which may be undermined. Perry and Shaw cite a case in which miliary tubercles were visible in the base of an ulcer. Cases of perforation have been reported by Clark, Perry and Shaw, Hebb and Krauss.

The third type of gastric lesion in tuberculosis is the granuloma. This is usually situated at the pylorus and may produce a stenosis. It is a tumor-like mass which on examination will show the characteristic picture of tuberculosis with giant cells. These masses contain few bacilli. Chalier describes a case of a tumor at the pylorus in which there was no tuberculous charge yet inoculations of the tissue into guinea pigs caused their death from tuberculosis. On account of the similarity in structure of these granulomata to those lesions in pyloric obstruction in the new-born, Chalier suggested a possible similar etiology. A typical case of granuloma is one described by Ortali. The patient was a farmer of 52 who had had stomach trouble for six months, eructations, pain an hour or two after eating and vomiting every two or three days soon after eating. No blood had been noticed in the stool or vomitus. There was slight evening temperature, no cough or night sweats, but diarrhea and constipation alternated and the man grew very thin. Lactic acid but no free hydrochloric acid was found in the stomach contents and the stomach was opened up on suspicion of cancer. The pylorus region was found the seat of a hard tumor studded with granulations. Gastroenterostomy relieved the patient of his disturbances but he succumbed two months later to tuberculous peritonitis. Ortali knows of only 24 cases on record of this tumor form of tuberculosis of the stomach.

The following cases are a few of several seen by the writer and are given as type cases to illustrate some of the points brought out in this paper.

Case I.—Symptoms of Hyperacidity. Male, 45 years old. Negative alcoholic, tobacco and venereal history. When first seen he had symptoms of hyperacidity. Dull pains came on immediately after meals and were relieved by alkalis. He had no cough. Slight expectoration. Slight fever and sweating at night. The history was of one year's duration. Examination showed an involvement at both apices with signs of cavity formation on the right side. This was confirmed by *x*-ray. The sputum contained tubercle bacilli. With proper hygienic and tonic treatment, the sweating and fever disappeared and simultaneously with this the gastric symptoms also disappeared.

Case II.—Symptoms of pylorospasm and dilatation. Female 35 years old. Four years previously she had had symptoms of pulmonary disease which was diagnosed as tuberculosis and pleurisy. At that time she had lost weight; she had had night sweats and slight fever but no cough. The *x*-ray confirmed the diagnosis of tuberculosis. The pleurisy disappeared under treatment. When I saw her she was having severe attacks of persistent vomiting. This time she had no fever, no night sweats and no cough. A diagnosis of pylorospasm and dilatation of the stomach was made. Frequent lavages caused a cessation of the vomiting. I saw her again two months after this when she had further attacks of vomiting. The same treatment was followed and the vomiting ceased. The *x*-ray showed the tuberculous process still present but in a quiescent stage.

Case III.—Symptoms of gastric ulcer. Male 40 years old. He gave a history of gastric ulcer one year previously. A posterior gastroenterostomy had been performed without benefit. No ulcer could be palpated. The symptoms continued unrelieved. An operation for postoperative adhesions was next performed, also without relief. His lungs had been examined during this time and had been found negative for signs of tuberculosis; when I saw him there was a decided change. The right side almost from apex to base was found consolidated. This was proven by the *x*-ray to be a tuberculous process with marked caseation. No tubercle bacilli were found in his sputum. The symptoms now were very typical of tuberculosis. The only explanation that can be given for the late appearance of the signs of tuberculosis is that he must have had some hidden or deep-seated focus that was lit up by the lowered resistance of the lungs following the two operations. What the gastric condition was due to is difficult to say. No ulcer could be palpated and so it is possible that the lesion might have consisted of very small ulcerations.

Case IV.—Symptoms of ulcer with hematamesis. Male 32 years old. He had complained of very severe epigastric pain for one year. This pain would come on from fifteen minutes to one hour after eating and at first it was relieved by alkalis. Later the pain became so severe that hypnotics had to be resorted to. When I saw him he was emaciated; he had been having night sweats but no cough and no fever. Both physical and *x*-ray examinations showed an active process at one apex. The sputum contained tubercle bacilli. In order to get a better insight into the cause of his gastric distress it was deemed advisable to examine his stomach contents. Before this could be done he had hematemesis and vomited about 1300 c.c. of bright blood. He died ten days afterward in spite of all treatment. Inasmuch as the appearance of the symptoms of gastric ulcer were coincident with those of tuberculosis it is reasonable to assume that the ulcer was on a tuberculous basis. This, of course, is not conclusive as no autopsy could be obtained.

In concluding it may be seen that from the physiological and pathological changes in the stomach that there exists very good cause for gastric symptoms in tuberculosis. There is hardly a symptom of gastric involvement that may not be simulated or produced by tuberculosis. These symptoms may vary from the slight transient gastric pains to symptoms of gastric perforation. The symptoms may be so slight or so severe as to prevent the examiner from looking beyond the stomach for the cause. In all cases it is advisable that a complete physical examination of the chest as well as of the abdomen should be made. If this cannot be done it should be insisted upon at least in those cases with simple symptoms that do not improve under the usual treatment and particularly in those cases where careful questioning has revealed the presence of some symptom suggesting tuberculosis.

IMPAIRMENT AND LOSS OF SEXUAL POWER IN ACROMEGALY.*

By WILLIAM A. BOYD, B.S., M.D.,

Baltimore, Md.

Assistant Neurologist, Mercy Hospital Dispensary; Assistant Psychiatrist, Phipps Psychiatric Dispensary, The Johns Hopkins Hospital.

Osler defines acromegaly as "a distrophy characterized by abnormal processes of growth, chiefly in the bones of the face and extremities." The oldest cases on record are those of Saucerotti-Noël, which were reported in 1772. Dr. Pierre Marie, a Frenchman and pupil of Charcot, announced to the profession his important clinical observations of this disease in 1885.[1] Edward Melchoir, however, has pointed out that Marie was possibly not the first to demonstrate a causal relationship between the hypophysis and acromegaly. He gives the credit of this to Minkowski[2] of Naunyn's clinic, who first clearly stated that an enlargement of the gland had been observed in all carefully examined cases.

Before the appearance of Marie's first memoir, a certain number of cases of this disease had been

*Read before the Neurological Section of the Baltimore City Medical Society, April 9, 1915, Baltimore, Md.

classed under such headings as Basedow's disease, cachexia, pachydermia, osteitis deformans, gigantism, and leontiasis ossea.

In 1890 Dr. Souza-Leite, a pupil and friend of Marie, collected and published such evidence as had accumulated respecting this disease. In this country Dr. Harvey Cushing has written much about this disorder; his monograph, "The Pituitary Body and Its Disorders," is a most valuable work, and has frequently been referred to in the preparation of this paper.[3]

Before coming to the principal portion of this paper, which, by the way, consists of mere figures, I will mention a few of the conceptions of acromegaly which deserve consideration.

There have been four different views regarding the nature of the disease, as follows:

1. At first Marie regarded the process as a general dystrophy; in his later papers published in 1888-1889 he attributed it to diminished function.

2. Massalongo in 1892, Tamburini in 1894, Benda in 1901, Modena in 1903, and Fisher in 1910 have championed the view that the condition is due to hyperfunction, and is often associated with an hypertrophy or adenomatous hyperplasia of the gland (pituitary), for it is not produced by destructive or malignant growths. According to Benda, Lewis, and Erdheim, the elements chiefly concerned in the hyperplasia are the eosinophilic cells, and there may actually be no gross enlargement of the gland.

3. Gauthier in 1892, Strümpell in 1897, Vassale in 1902, Guerrini in 1905, and Cagnetto in 1907 regard the acromegalic changes as due to some underlying nutritional disorder which affect metabolic processes, the hypophyseal enlargement being a consequence and not the cause of the malady. Cushing states that this view must be accepted by all, though it is something of a quibble, for just as in hyperthyroidism, there must be some underlying biochemical disturbance which brings about the glandular hyperplasia.

4. A few, as Silvestrini and Arnold in 1894, Warda in 1901 and Petrén in 1907, on the basis of presumably negative hypophyseal findings, conclude that acromegaly bears only an accidental relationship to pituitary lesions. Cushing states in his monograph that most of the circumstantial evidence in our possession points in the direction of an oversecretion, whether normal or pathological, and this is at least the most acceptable hypothesis.

In preparing this paper I have reviewed and studied 85 reported cases, but of these there are 20 in which there is no mention regarding the sexual function, therefore 65 cases only are used as a basis for this study.

The cases studied have been reported in literature by the following observers: Marie 8 cases, Marie and Souza-Leite 2 cases, Souza-Leite 3 cases, Cushing and his collaborators (Goetsch, Crowe, Homans, and Jacobson) 29 cases, and one case each by Verstraeten, Virchow, Freund, Shultze, Binet, Rogier, Pechadre, Farge, Erb, Hadden and Ballance, Godlee, Wilks, Tresilian, Wadsworth, Lanceraux, Fritsche and Klebs, Lombroso, Ruttle, Verga, Chalk, Fleming, Bramwell, and Hurt.[4]

As regards sex, the cases studied are almost equally divided, there being 34 males and 31 females.

The ages of the patients at the time they came under observation were as follows: In 6 cases the age was not given; 2 cases between the ages of fourteen and twenty; 13 cases between the ages of twenty and thirty; 24 cases between the ages of thirty and forty; 17 cases between the ages of forty and fifty; 2 cases between the ages of fifty and sixty; 1 case between the ages of sixty and seventy; total 65. It would therefore seem from the reports that the majority of cases came under observation between the ages of thirty and fifty.

Of the sixty-five cases the social condition of twenty-two males and eight females was not mentioned. There were seven single males and eight single females, eight married males, ten married females, and two widows.

In disorders like acromegaly having a very slow progression, it is very difficult to say just when the attack began.

In the report of some cases only the statement of the patient could be had as to the date of the beginning of the disease, as it, in many cases, was far advanced when the patient was first seen by the physician.

The following are the ages as reported when the disease began:

Males: One case each at 15, 23, 28, 29, 30, 33, 34, 36, 40, 45, 52; 3 cases at 18; 2 cases at 20; 3 cases at 24; 2 cases at 25; 3 cases at 27; 2 cases at 31, and 2 cases at 32; total 28. As will be noted, the attack began in 20 out of 28 cases between the ages of twenty and forty.

Females: One case each at 14, 15, 16, 17, 19, 21, 22, 23, 27, 29, 31, 32, 37, 38, 39, 43, 49, 56, 57; 3 cases at 20; 3 cases at 24; two cases at 25; 2 cases at 28, and 2 cases at 35; total 31. According to the above figures 19 out of 31 cases began between the ages of twenty and forty.

In four cases the sex was given as male and two cases as female, but the date of the beginning of the illness in each case was not given.

Cushing states that "unquestionably the interrelation between the hypophysis and testes or ovary appears on clinical grounds to be more intimate than between any other two members of the series, and in the large majority of cases there has been some impairment or loss of potentia sexualis in the male or female. Symptoms referable to the reproductive functions may apparently long antedate those attributable even to the hypophysis itself."

The case reports abound with examples of imperfectly acquired secondary sexual characteristics when the hypophyseal lesion antedates puberty, and of resultant amenorrhea or impotence with retrogressive sexual changes when the malady develops after the acquirement of adolescence.

Males in which there was no sexual impairment, social condition not mentioned, 12; females in which there was no sexual impairment, social condition not mentioned, 2. Males, married, in which there was no sexual impairment, 2; females, married, in which there was no sexual impairment, 2. Males, single, in which there was no sexual impairment, 2. Total number of cases having acromegaly, both sexes, in which there was no sexual impairment, 20. Total number of cases having acromegaly, both sexes, in which there was a loss of or some impairment of the sexual function, 65. Total number of cases studied and reviewed, 85. Of the 50 cases of males studied 34, or 68 per cent., had loss or some impairment of sexual power; of the 35 cases of females studied 31, or 89 per cent., had loss or some impairment of sexual power.

Of the 34 males having loss or impairment of sexual power 9 were reported as impotent, and ac-

cording to social condition were divided as follows: Married, 4; single, 3; social condition not given, 2.

Of the 31 females having loss or impairment of sexual power 23 were reported as impotent, and were divided as follows: Married, 8; widowed, 1; single, 6; social condition not given, 8.

Number of cases in which sexual power was somewhat diminished (anaphrodisia, etc.), 19. Males: married, 1; single, 2; social condition not given, 9; total males, 12. Females: married, 2; single, 3; widowed, 1; social condition not given, 1; total females, 7.

Number of cases in which there was no sexual power at the age of puberty: Males, 3; females, 1; total, 4.

Number of years which elapsed between the time the catamenia was established and the time when the amenorrhea became permanent according to social condition: Married, one patient, each 3, 6, 18, 19, and 23 years. Single, two patients, 2 years; one patient, each, 7, 12, 15, and 24 years. Social condition not given, 1 patient each, 2 and 11 years.

Number of cases in which the date of the beginning of the establishment of menstruation was not noted in the case reports: Married, 5; single, 2; widowed, 2; social condition not mentioned, 6.

The ages when the amenorrhea became permanent are given as follows: Married, 18, 19, 20, 24, 29, 32 (2), 37, 38, and 39; single, 16, 17, 21, 24, 28 (2), and 37; widowed, 42 and 43; social condition not mentioned, 18, 22, 25, 27, 35, 36, and 37 (2).

Intervals of years between the date of the establishment of the menses and the date of permanent amenorrhea: Two cases, 2 years; one case each 3, 6, 7, 11, 12, 15, 17, and 18 years.

Number of cases in which there was an absence of secondary sexual characteristics: (masculine voice, pubic and axillary hair, adolescent beard, enlargement of the genitals, etc.) Males, married, 2; single, 2; social condition not given, 1; females: married, 1; single, 2; widowed, 1.

Number of cases in which at autopsy some abnormality of the genitalia was found which had not before been noted: Males, married, 1; single, 2; females: married, 1.

Number of cases in which there was no sexual power: Males, social condition not given, 1.

Number of cases in which the genitalia were of abnormal size: Males, married, 1; single, 1; social condition not given, 1; females: married, 2; single, 1; social condition not given, 1.

Number of cases in which the genitalia were undeveloped or atrophied: Males: single, 3; social condition not given, 3; females: married, 3; single, 5; social condition not given, 1.

Of the 31 females whose cases have been studied 28 of them have had loss or some impairment of potentia sexualis: Married, 10; single, 8; widowed, 2; social condition not given, 8.

Cases in which a permanent amenorrhea had persisted: Married, 7; single, 5; social condition not mentioned, 6.

Cases in which amenorrhea was temporary: Married, 1; single, 3; widowed, 1; social condition not mentioned, 2.

ARTIFICIAL INFANT FEEDING.

By J. Epstein, M.D.,
Brooklyn, New York.

The best food for an infant is good milk from a healthy mother. When the supply of breast milk is insufficient for the proper nourishment of the infant, partly breast feeding and partly bottle feeding is the next best food. Quite a large number of infants are deprived of maternal feeding and are fed on all kinds of "formulas" which frequently not only fail to supply the proper food for the normal growth and development of the infant but cause various gastrointestinal disturbances.

An infant may survive a wrong diagnosis, it may tolerate poor therapeutics, but it will never take bad feeding for a long time without giving rise to loss in weight, marasmus and ultimate dissolution.

The following cases illustrate improper feeding and its effect on the health and development of the infants.

Case I.—Baby M. M., 11 weeks old, a large infant at birth, weight unknown, full term and normal labor, was brought to me because of constipation, constant crying and loss in weight. Feeding history:

1. Breast fed for 3 weeks. Mother thought her milk gave out and the infant was given the following milk mixtures:

2. Whole milk, 1 ounce; lime water, 1 ounce; milk sugar, ½ teaspoonful; water, 3 ounces. Given at each feeding twice a day for four weeks.

3. Whole milk, 2 ounces; lime water, 1 ounce; milk sugar, ½ teaspoonful; water, 4 ounces. Given at each feeding 3 times a day for two weeks.

4. Whole milk, 3 ounces; lime water, 1 ounce; milk sugar, ½ teaspoonful; water, 4 ounces. Given at each feeding 4 times a day for two weeks.

At the end of eleven weeks the infant weighed 6 pounds and 15 ounces. On examination I found the infant suffering from no other illness than starvation. I prescribed a proper food suitable for the age and condition of the infant and there was no more cause for crying, the constipation, which was the result of lack of food, was relieved without any medication and the baby rapidly gained in weight.

Case II.—G. E., 9 weeks old, full term and normal labor, birth weight unknown. Baby almost constantly cried since birth, weighing at 9 weeks 6 pounds and 13 ounces. Feeding history:

1. Was never breast fed.

2. For the first 2 weeks the baby was given an infant food and water according to directions on the label. The infant cried all the time and the food was changed to:

3. Zwieback in water strained and given at irregular hours for a few days. The infant resented this food by still more crying, and it was then put on:

4. Whole milk, 1 cup; barley water, 2 cups. The entire quantity was given during 24 hours.

On examining the baby I found nothing that it wanted except proper food given at regular hours and not a pure carbohydrate diet, which had very little food value and which the infant was probably unable to digest. It is an indefinite and unscientific method to order a cup of milk and two cups of barley water for 24 hours to be given a little each time the baby cries. The infant's food must be suitable to its digestive ability and should be given in exact quantities at regular hours.

Case III.—M. E., aged 2 months, full term instrumental delivery, birth weight 9 pounds and 8 ounces. For 6 weeks before the infant came under my observation it vomited after each feeding and was constipated. Feeding history:

1. Breast fed for 3 days.
2. Top milk, 5 teaspoonfuls; lime water, 1 ounce; water, 2 ounces. This was given every 2 hours for 2 weeks, but the baby began to vomit and the food was changed to:
3. Top milk, 5 teaspoonfuls; barley water, 2 ounces. Every 2 hours for 2 weeks; vomiting persisted and the infant was put on:
4. Condensed milk, ½ teaspoonful; barley water, 3 ounces. Every 3 hours for one week. Baby continued to vomit and the food was changed again to:
5. An infant food, 2 teaspoonfuls; water, 4 ounces. Given every 2½ hours. The weight at the end of 2 months was 6 pounds and 4 ounces.

In an effort to find a suitable food for the baby's digestion the real trouble was entirely overlooked by the attending physician for on examination I found this to be a case of pyloric stenosis.

CASE IV.—S. F., 4 months of age, a large baby at birth, weighing 10 pounds, was brought to me because of constipation and an eczema on the face and thighs which resisted treatment with all kinds of ointments and lotions. Feeding history:
1. Breast fed for 6 weeks, then
2. Whole milk and water gradually increased in quantity and strength till for the last 4 weeks the baby received 48 ounces of whole milk, 48 ounces of water with 6 teaspoonfuls of granulated sugar in 24 hours. At 4 months the weight was 15 pounds and 7 ounces.

This infant was given entirely too much food and was in a miserable condition from the itching of the eczema, sleeplessness, and constipation. I reduced the food to 48 ounces in 24 hours, giving 2 per cent. fat and 5 per cent. sugar and still the baby gained in weight so that at six months it was 17 pounds and 1 ounce. A teaspoonful of rhubarb and soda mixture relieved the constipation and a soothing ointment to the eczema cured the infant in a short time.

CASE V.—S. M., 5 weeks old, first baby, full term and normal labor, birth weight 5 pounds and 8 ounces, and at 5 weeks 5 pounds and 1 ounce. The infant was brought to me because of constipation, vomiting and restlessness. Feeding history:
1. Breast fed for 2 weeks, then
2. Upper 1 ounce of milk; whole milk, 1 ounce; lime water, ½ ounce; milk sugar, ½ ounce; water, 7½ ounces. Given 1 ounce every 2 hours.

For three weeks the infant was given 10 ounces of food a day with 2 ounces of milk, while it really needed 20 ounces of food a day with about 10 ounces of milk. It also evidently received too much fat for its digestive capacity. On increasing the amount of food and starting with a lower fat, the vomiting ceased, the constipation which was probably due to too little food was relieved and the baby gained in weight.

CASE VI.—W. J., aged 6 months, full term and normal labor, weight unknown. For 2 months before it came under my care the baby vomited after every feeding, lost in weight and was constipated. Feeding history:
1. Breast fed for 4 months and weighed 13 pounds and 1 ounce; then the baby vomited for several days and the family physician advised weaning and prescribed the following feeding:
2. Milk, 6 ounces after removing the upper 6 ounces from a quart bottle; milk sugar, 3 teaspoonfuls; milk of magnesia, 1 teaspoonful; peptogenic powder, 1 tube; water, 18 ounces. Given 4 ounces every 2½ hours for 2 weeks. The baby vomited and the food was changed from this one, very low in fat, to one high in fat.
3. Upper 10 ounces of milk; milk sugar, 1 tablespoon; lime water, 1 tablespoonful; water, 22 ounces. Given in 24 hours for one week, the vomiting became worse and the baby was put on:
4. Condensed milk, 1 teaspoonful; a little whole milk; lime water, 1 teaspoonful; water, 4 ounces. Every 2½ hours.

The vomiting persisted and the weight was now, at 6 months, 11 pounds and 5 ounces. A great injustice was done to this infant by taking it off the breast. Fortunately the mother kept up the flow of milk by the use of a breast pump, and I immediately put the infant on a mixed feeding, partly breast milk and partly a suitable milk mixture, fed every four hours, the stomach was washed once a day, the vomiting stopped, the constipation was relieved, and the baby gained in weight.

CASE VII.—E. L., 2½ months old, full term and normal labor, birth weight 6 pounds and 8 ounces and at 2½ months 7 pounds and 6 ounces, was brought to me because of poor gain in weight. Feeding history:
1. Nursed for 3 days then the "milk gave out" and the infant was put on:
2. Whole milk, 2½ tablespoonfuls; cane sugar, 1 teaspoonful; barley water, 1 cup; a pinch of salt. Three such cups of food was given during 24 hours.

Though the baby gained a little in weight in the two and a half months, it would have gained a great deal more if sufficient milk had been given. It is a very poor method of feeding by ordering milk by the tablespoonful and barley water by the cup. An exact number of ounces of milk, sugar, and water should be ordered and equally divided into the number of feedings necessary in 24 hours and fed at regular intervals.

CASE VIII.—O. M., 4 weeks old, first baby, full term and normal labor, birth weight 6 pounds and 6 ounces. Feeding history:
1. Nursed for 2 weeks. During this time the baby would take the breast in the mouth and after a few minutes' nursing would drop it and cry for a while, then would try again to nurse and drop it again crying. The infant was then weaned and put on:
2. Upper 2 ounces of milk; lime water, 1 ounce; milk sugar, 1 ounce; water, 16 ounces. Divided into 10 feedings and given every 2 hours. At the end of 4 weeks the baby's weight was 4 pounds and 9 ounces, vomited frequently and had slight diarrhea.

This infant evidently did not find enough milk in the breasts and after each attempt to nurse would drop the breast in disappointment. The milk mixture given was too poor in milk and perhaps too rich in fat. I advised the mother to give the breast four times a day and prescribed six bottle feedings a day. The mother had sufficient milk for four feedings, the baby gained in weight and the digestion rapidly improved.

CASE IX.—M. J., 7 months old, full term and normal labor, weight unknown. I was consulted because the baby's weight at 7 months was only 9 pounds and 7 ounces. Feeding history:
1. Nursed for 1 month, then weaned and put on:
2. Condensed milk, 2 teaspoonfuls; water, 5 ounces. Given every time the baby cried for 1 month. The infant vomited frequently and the food was changed to:
3. Whole milk, 15 ounces; water, 7 ounces; peptogenic milk powder, 1 measure, boiled together and given about 2 ounces every 2 hours for several weeks. Baby vomited and lost in weight.
4. Whole milk, 8 ounces; well cooked oatmeal, 2 tablespoonfuls; water, 16 ounces. Given in 24 hours for one week. The baby cried a great deal and vomited frequently and the food was then changed again to:
5. Condensed milk, 10 ounces; sugar, 1 tablespoonful; barley flour, 1 tablespoonful; water, 30 ounces.

It is really a wonder that the baby survived such frequent changes in feeding and such a poor variety of food.

CASE X.—R. M., 2 months old, first baby, full term and normal labor, birth weight 5 pounds and 8 ounces, vomited frequently and lost in weight. Feeding history:
1. For the first three days after birth a certain tea was given to serve as a food and to keep the baby asleep.
2. Barley water for 1 week, given a little every 2 hours. Baby vomited a great deal and the food was then changed to:
3. Whole milk, 6 ounces; barley water, 12 ounces. Given during 24 hours a little at a time for 3 weeks.

The baby did not do well on this feeding and was put on:

4. Condensed milk, 1 teaspoonful; water, 2½ ounces. Given every 2 hours. On this food there was vomiting and diarrhea, and it was changed again to:

5. Whole milk, 1½ ounces; water, 4½ ounces. Every 2 hours.

This infant began its earthly existence with an infusion of some seed, probably fennel seed, as a food; evidently the baby did not thrive on it and barley water was substituted, which had very little food value and was probably not digested properly. A fairly good milk mixture was then given, but it was not given in proper amounts or at exact intervals, a little being given every time the baby cried. The infant vomited, had slight diarrhea, and cried a great deal. As a remedy to the baby's ills condensed milk was given which made a bad case worse, then again milk was given. The result was that for two months the baby had no proper food or proper feeding. I put the baby on a suitable milk mixture given at regular hours, the vomiting ceased and the baby gained in weight.

The above ten cases represent only a few of a large number of babies that came under my care who were healthy at birth but were made ill by improper feeding. The majority of my little patients suffered from under feeding; only a few were overfed; while others received fairly good milk mixtures but the food was given in the wrong way, that is any time the baby cried and as much as it wanted.

In the artificial feeding of infants success may be obtained by adhering to the following principles:

1. Proper quantity of food according to the age, weight, and general condition of the infant.

2. Proper quality of food, neither too rich nor too poor in the normal constituents of milk.

3. Proper regularity of feeding, every two, three, or four hours, according to the age and the digestive ability of the infant.

4. Proper care in the keeping of milk at the right temperature and the cleanliness of the bottles and nipples; the food when served to the infant must be at body temperature.

5. Simplicity; the baby does not want anything else than plain milk, sugar, and water, all other forms of milk, ready-made foods, cereals, and lime water are not necessary. I have never used anything else in the artificial feeding of healthy infants but raw certified milk, sugar, and water. When the baby is about six months old I give once a day, besides the ordinary milk mixtures, a thick, well-cooked cereal fed with a spoon. The cereal serves to add some food value, it stimulates the digestive tract to a proper digestion of starch, and last, but not least, it breaks up the monotony of the infant's diet.

In prescribing milk mixtures I make use of the following different modifications:

1. Feeding with simple dilutions of whole milk.

2. Feeding with dilutions of top milk.

3. Feeding according to percentage formulas.

4. Feeding with humanized milk, that is cow's milk with the percentage composition of human milk which is prepared by using the upper 15 ounces of a quart bottle of raw, certified milk after standing undisturbed for about six hours at a temperature of from 40° to 50° F. This upper 15 ounces is diluted with an equal volume of cool, boiled water to which the proper amount of milk sugar has been previously added. In an article in the MEDICAL RECORD for May 29, 1915, I described its preparation in full.

175 HEWES STREET.

AN INTERESTING OBSTETRICAL CASE.

BY ISIDOR ECKERT, M.D.,

NEW YORK.

MRS. M. M., aged 24 years, engaged me to attend her in her first confinement almost three and one-half years ago. After the usual antepartum examination, I informed her that everything was normal and that, barring any unforeseen complication, she should have a normal delivery at full term. She was later influenced to change her plans and entered one of our large hospitals to be confined there by one of its attending obstetricians. After she had been in labor but a few hours, the obstetrician told her that she was suffering from a deformed pelvis and could never deliver her baby and that a cesarean section would have to be performed. The operation was successfully performed and a 6½ pound living boy was born, the mother making an uneventful recovery.

Patient again became pregnant and on consulting her former attending obstetrician was told that a cesarean section would again have to be done. During the course of her pregnancy, she also consulted me and, in her conversation, recalled to my mind what I had told her during her first pregnancy and said if I could assure her of a normal delivery at the termination of this pregnancy, she desired me to attend her in her second confinement. After the usual antepartum examination, I again informed her that, barring any unforeseen complication, she should have a normal delivery. On Friday, Aug. 13, 1915, after an actual labor lasting about twelve hours, she gave birth to a living boy, weighing 7¼ pounds. In this connection, it is also interesting to mention the fact that 1 c.c. pituitrin was given intramuscularly to hasten delivery during a tedious perineal stage.

This case is reported to show, firstly, how as a result of a grossly inaccurate diagnosis a patient was subjected to the risks of a major surgical operation; secondly, the possibility of a normal delivery following a cesarean section, and thirdly, the comparative safety in the use of pituitrin in properly indicated conditions even in a previously wounded uterus.

321 EAST FOURTH STREET.

Raynaud's Syndrome: Raynaud's Disease.—O. T. Osborne states that Raynaud's disease is not a distinct entity; it is a syndrome caused by the disturbance of one or more internal secreting glands. There is primarily no real disease of the blood vessels, but the vasomotor control is so abnormally disturbed that most profound contraction of certain blood vessels may occur in different parts of the body, perhaps more or less coincident with abnormal dilatation of other blood vessels. If the contracted blood vessels are peripheral the parts more or less lose their function and show various trophic disturbances. This blood-vessel spasm may occur in the internal organs of the body as well as peripherally, though much less frequently and more difficult of diagnosis. The syndrome is probably due to disturbances of more than one of the ductless glands of the body that have internal secretion, but there is always apparently some disturbance of the thyroid gland, perhaps a diminution of the vasodilator stuff of this gland. Judiciously applied, thyroid treatment improves the majority of cases, perhaps all, and cures some cases. Nitroglycerin is always of temporary benefit and local heat is always of immediate benefit.—*American Journal of the Medical Sciences.*

The Relationship of Infantile and Adult Death Rates.—Brownlee has made extensive studies of birth and death rates. He concludes that the conditions which produce a high infantile death rate are exactly those conditions which depress at the same time the vitality of the whole adult population. "All the evidence is against the view that a high infantile mortality produces a healthier population at adult ages."—*The Journal of Hygiene.*
